The most important question to be answered is how the Cu,Zn-SOD active site can accelerate both the oxidation and reduction of $\text{O}_2^{\bullet-}$, required for the rapid disproportionation. Such a dual role would be made possible by the bimetallic system, since any monometallic system can only activate either the oxidation or reduction of $\text{O}_2^{\bullet-}$. The important role of Zn(II) ion in the bimetallic system to activate both the oxidation and reduction of $\text{O}_2^{\bullet-}$ has been implicated by a well-characterized SOD model, that is, an imidazolate-bridged Cu(II)–Zn(II) heterodinuclear complex containing a dinucleating ligand, Hbdpi {Hbdpi = 4,5-bis[di(2-pyridylmethyl)-aminomethyl]imidazole}, shown in Figure 9 [182]. The Cu(II)–Zn(II) distance of 6.197(2) Å in the Cu(II)–Zn(II) heterodinuclear complex agrees well with that of native Cu,Zn-SOD (6.2 Å), and each metal has the pentacoordinate geometry with the imidazolate nitrogen, two pyridine nitrogens, the tertiary amine nitrogen and a solvent (MeCN or H_2O) [182]. The ESR spectrum of complex of the Cu(II)–Zn(II) heterodinuclear complex gave the well-defined ESR parameters ($g_{\parallel} = 2.10$, $g_{\perp} = 2.24$, $|A_{\parallel}| = 11.7$ mT and $|A_{\perp}| = 12.4$ mT), which indicate that the Cu(II) ion in the complex has a trigonal bipyramidal environment and a d_{z^2} ground state

Figure 9. ORTEP view of [CuZn(bdpi)(MeCN)₂](ClO₄)₃·2MeCN [182]. The hydrogen atoms are omitted for clarity.

following the criteria given by Bencini et al. [183], in agreement with the X-ray structure in Figure 9 [182]. The observation of a well-defined ESR spectrum also confirms that the complex retains its imidazolate-bridged Cu(II)–Zn(II) heterodinuclear structure and that it is not a 1:1 mixture of Cu(II)–Cu(II) and Zn(II)–Zn(II) homodinuclear complexes. The Cu(II)–Zn(II)SOD model complex, which has a coordination site available for the binding of superoxide as shown in Figure 9, exhibits the highest activity among the structurally established SOD models reported so far [181, 184, 185].

A large positive shift (about 0.2 V) in the $E_{1/2}$ value of the Cu(II)–Zn(II) complex is observed compared with the corresponding Cu(II) mononuclear complexes [172]. This indicates that an important role of Zn(II) ion in the imidazolate-bridged Cu(II)–Zn(II) complex is to accelerate an outer-sphere electron transfer from $O_2^{\cdot-}$ to produce the Cu(I)–Zn(II) complex, when the free energy change of electron transfer becomes thermodynamically more favorable compared with that without Zn(II) ion. The presence of Zn(II) which can act as a Lewis acid is also able to accelerate an electron transfer from the Cu(I)–Zn(II) complex to $O_2^{\cdot-}$, since $O_2^{\cdot-}$ can form a complex with metal ions acting as a Lewis acid to accelerate the electron transfer reduction of $O_2^{\cdot-}$ (see above) [137, 138]. Such an acceleration for the reduction of $O_2^{\cdot-}$ can also be attained by a Brønsted acid instead of a Lewis acid since Valentine et al. reported that the reduction of $O_2^{\cdot-}$ for the zinc-deficient SOD form is acid-catalyzed [173, 186]. Thus, the essential role of Zn(II) ion in SODs is suggested to accelerate both the oxidation and reduction of superoxide by controlling the redox potentials of Cu(II) ion and superoxide in the catalytic cycle of SOD as shown in Scheme 10 [182]. A similar effect is also expected for another copper ion in the Cu(II)–Cu(II) homodinuclear complex containing the same Hbdpi ligand [182]. The role of Zn(II) ion may also lie in structural stabilization of the enzyme. The exact catalytic role of Zn(II) ion in SODs has yet to be examined in detail.

The binding of $O_2^{\cdot-}$ to Cu(II) ion can facilitate the further reduction of $O_2^{\cdot-}$ by Cu(I) ion to O_2^{2-} to give a $\mu\text{-}\eta^2\text{:}\eta^2$ -peroxodicopper complex [162, 187], which has been confirmed to exist in the enzyme active site of oxyhemocyanin [188, 189]. The

Scheme 10.

Scheme 11.

reaction of $[\text{Cu}^{\text{I}}\text{L}](\text{PF}_6)$ $\{\text{L} = N,N\text{-bis}[2\text{-(2-pyridyl)ethyl}]\text{-2-phenylethylamine}\}$ with O_2 in THF at -80°C was reported to give the $\mu\text{-}\eta^2\text{:}\eta^2\text{-peroxodicopper}$ complex, $[\text{Cu}^{\text{II}}_2(\text{O}_2^{2-})\text{L}_2](\text{PF}_6)_2$, the formation of which was confirmed by spectroscopic analyses [190, 191]. The kinetic study on formation of the peroxo complex indicates that the reaction of the Cu(I) complex and the monomeric superoxocopper(II) complex is rate-determining, as shown in Scheme 11 [191]. A superoxocopper(II) complex with a sterically hindered ligand which can prevent formation of the $\mu\text{-}\eta^2\text{:}\eta^2\text{-peroxodicopper}$ complex was isolated and the X-ray structure was determined to show a side-on binding of $\text{O}_2^{\bullet-}$ the Cu(II) ion [192]. The strong interaction between $\text{O}_2^{\bullet-}$ and the Cu(II) ion makes it possible to reduce $\text{O}_2^{\bullet-}$ to O_2^{2-} further by another $[\text{Cu}^{\text{I}}\text{L}]^+$, leading to the formation of the $\mu\text{-}\eta^2\text{:}\eta^2\text{-peroxodicopper}$ complex (Scheme 11). The change in the one-electron reduction potential of $\text{O}_2^{\bullet-}$ by the binding to the Cu(II) ion has yet to be determined.

The further intramolecular electron transfer from the two Cu(II) ions to O_2^{2-} in the $\mu\text{-}\eta^2\text{:}\eta^2\text{-peroxodicopper}$ complex may result in the O–O bond cleavage to give the bis- $\mu\text{-oxodicopper(III)}$ complex, which is suggested to be the actual reactive intermediate for the efficient benzylic ligand hydroxylation as also shown in Scheme 11 [191]. Interconversion between the $\mu\text{-}\eta^2\text{:}\eta^2\text{-peroxodicopper}$ complex and the bis- $\mu\text{-oxodicopper(III)}$ complex was observed using the $i\text{-Pr}_3\text{TACN}$ ligand ($i\text{-Pr}_3\text{TACN} =$

1,4,7-triisopropyl-1,4,7-triazacyclononane) just by changing the solvent between CH_2Cl_2 and THF, where the oxidative *N*-dealkylation occurs efficiently from the bis- μ -oxodicopper(III) complex [193, 194]. Thus, these two forms of the active oxygen dicopper complex may be similar in their energies.

1.3.4 Acid Catalysis in Overall Reactions

It has been extremely difficult to distinguish between conventional ionic or concerted mechanisms and electron transfer mechanisms, since the final products and kinetics are often the same regardless of the mechanisms. If an electron transfer step is the rate-determining step in an overall reaction, it would be almost impossible to detect the initial products of electron transfer because of the extremely short lifetimes. In such a case, the mechanistic distinction seems to be dubious and possibly even meaningless, unless one mechanism provides a more quantitative description of the energetic profiles of the reactions than the other does. If a particular reaction, which was previously formulated as an ionic or concerted reaction, undergoes a rate-determining electron transfer from an electron donor to an acceptor, which is catalyzed by metal ions, the dependence of the rate constant on the metal ion concentration for the overall reaction would be the same as that observed in the electron transfer reduction of the same electron acceptor. Hence the comparison of the catalytic function of metal ions in electron transfer reactions with that in apparently polar or concerted reactions of the same substrate would provide valuable insight into the mechanistic viability of electron transfer (see below).

Diels–Alder reactions via electron transfer

Diels–Alder reactions are usually regarded as concerted processes where the interaction between HOMOs of dienes and LUMOs of dienophiles determines the reactivity [195–197]. When electron-rich dienes having high-lying HOMOs react with electron-deficient dienophiles having low-lying LUMOs, however, electron transfer from the diene to the dienophile in the charge-transfer complex formed between the diene and the dienophile plays an important role as the activation step [198–205]. The interaction of metal ions with radical anions of dienophiles may enhance the electron affinity of the dienophiles so that electron transfer may provide a favorable reaction pathway for such dienophiles. In fact, the $[4 + 2]$ cycloaddition of 9,10-dimethylantracene (DMA) with *p*-benzoquinone (Q) occurs efficiently in the presence of $\text{Mg}(\text{ClO}_4)_2$ to yield the adduct selectively (Eq. 21) [132]:

although *p*-benzoquinone derivatives have been regarded as inert or weak dienophiles [206, 207]. The $[4 + 2]$ cycloaddition of anthracene and 9-methylantracene

with other *p*-benzoquinone derivatives ($X-Q$: $X = 2,5\text{-Cl}_2$ and $2,5\text{-Me}_2$) also occurs efficiently in the presence of $\text{Mg}(\text{ClO}_4)_2$ to yield the corresponding adducts [132]. The observed second-order rate constant (k_{obs}) increases with increase in $[\text{Mg}^{2+}]$ to exhibit a first-order dependence on $[\text{Mg}^{2+}]$ at low concentrations, changing to a second-order dependence at high concentrations, as shown in Figure 7b [132]. There is a striking similarity with respect to the dependence of k_{obs} on $[\text{Mg}^{2+}]$ between the electron transfer reaction (Figure 7a) and the Diels–Alder reaction (Figure 7b), despite the large difference in their reactivities. Thus, the dependence of k_{obs} on $[\text{Mg}^{2+}]$ can be expressed by Eq. 14 in which k_{et} should be replaced by k_{obs} . The plot of $k_{\text{obs}}/[\text{Mg}^{2+}]$ vs. $[\text{Mg}^{2+}]$ as employed for the Mg^{2+} -catalyzed electron transfer also gives a straight line for the Diels–Alder reaction of DMA with Q [132]. The K_2 values obtained from the linear plots for the Diels–Alder reactions of DMA with $X-Q$ in MeCN at 298 K agree with those obtained directly from the spectral change of $X-Q^{\cdot-}$ in the presence of Mg^{2+} as well as those determined from the electron transfer reactions [132]. Such agreements for each quinone strongly suggest that the Mg^{2+} -catalyzed electron transfer from anthracenes to $X-Q$ is a rate-determining step of the Diels–Alder reactions as shown in Scheme 12. The electron transfer from DMA to Q is catalyzed by the complexation of Mg^{2+} with $Q^{\cdot-}$. The radical ion pair produced in the Mg^{2+} -catalyzed electron transfer yields the Diels–Alder ad-

Scheme 12.

duct via radical or ion coupling, accompanied by regeneration of Mg^{2+} . In contrast to the case of Mg^{2+} -catalyzed electron transfer from (TPP)Co to Q (Eq. 13), Mg^{2+} appears only in the rate equation and not in the stoichiometric equation for the Diels–Alder reaction. According to Scheme 12, the K_2 values should be the same, irrespective of anthracene derivatives or electron donors, since the formation of the 1:2 complex of $\text{Q}^{\cdot-}$ and Mg^{2+} is independent of anthracene derivatives or electron donors. In fact, the K_2 values derived from the Diels–Alder reactions of DMA, 9-methylanthracene and anthracene with Q in acetonitrile at 333 K are the same ($K_2 = 2.1 \pm 0.3 \text{ M}^{-1}$), despite the significant difference in their reactivities [132].

The catalytic role of Mg^{2+} in Scheme 12 is ascribed to the 1:1 and 1:2 complex formation of $\text{Q}^{\cdot-}$ and Mg^{2+} , which results in an increase in k_{obs} with an increase in $[\text{Mg}^{2+}]$, exhibiting first- and second-order dependences on $[\text{Mg}^{2+}]$, respectively (Figure 7). This contrasts with the Lewis acid catalysis in conventional concerted Diels–Alder reactions, in which the catalyst is believed to activate dienophiles (not the radical anions) by coordination to the acidic metal center [208–212]. However, the exact catalytic mechanism of numerous Lewis acid-catalyzed Diels–Alder reactions [208–212] has yet to be clarified, including a possible contribution of Lewis-acid catalyzed electron transfer step.

Lithium perchlorate in diethyl ether has also been reported to accelerate Diels–Alder reactions significantly and this system has been applied to obtain Diels–Alder adducts that were inaccessible via conventional means [213–219]. A linear dependence of k_{obs} on $[\text{Li}^+]$ is observed for the Diels–Alder reaction of DMA with acrylonitrile in $\text{LiClO}_4\text{--Et}_2\text{O}$ solution, while a second-order dependence of k_{obs} on $[\text{Li}^+]$ is involved for the reactions with fumaronitrile and dimethyl acetylenedicarboxylate [216]. This suggests the possible contribution of Li^+ -catalyzed electron transfer step in the Diels–Alder reaction as the case of Mg^{2+} -catalyzed Diels–Alder reaction in Scheme 12. However, such an electron transfer mechanism has not been confirmed in the Li^+ -catalyzed Diels–Alder reactions.

Redox reactions via metal ion-catalyzed electron transfer

The effects of metal ions such as Mg^{2+} and Zn^{2+} ions on hydride transfer reactions from NADH model compounds to substrates have attracted considerable interest in relation to the role of metal ions in the redox reactions of nicotinamide coenzymes [220]. Hydride transfer reactions from NADH analogues to organic oxidants such as *p*-benzoquinone derivatives have been shown to proceed via sequential transfer of electron, proton and electron in the charge-transfer (CT) complexes formed between NADH analogues and the organic oxidants based on the kinetic comparison with the electron transfer reactions between NADH and one-electron oxidants as well as the kinetic isotope effects for the proton transfer step [221, 222]. Negative activation enthalpies have been observed for hydride transfer reactions from NADH analogues to 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) in chloroform (the lower the temperature, the faster the rate), indicating unequivocally that the CT complex is a true intermediate for the hydride transfer reaction [223, 224].

The effects of Mg^{2+} on hydride transfer reactions from a typical NADH model compound, 1-benzyl-1,4-dihydronicotinamide (BNAH), to substrates are complex

Scheme 13.

[225]. When a strong organic oxidant such as 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ) is employed as a hydride acceptor, the addition of Mg^{2+} to the BNAH–TCNQ system in anhydrous MeCN causes a significant decrease in the reaction rate [223]. The observed rate constant of hydride transfer from BNAH to TCNQ decreases with increase in $[\text{Mg}^{2+}]$ to reach a constant value which is 23 times smaller than that in the absence of Mg^{2+} . Such a retarding effect of Mg^{2+} is well interpreted by formation of the 1:1 complex between BNAH and Mg^{2+} , in which the electron donor ability of BNAH is diminished significantly [225], and thereby free BNAH undergoes the hydride transfer reaction via sequential transfer of electron, proton and electron as shown in Scheme 13 [213]. In this case, Mg^{2+} cannot act as a catalyst, since no complex is formed between $\text{TCNQ}^{\bullet-}$ and Mg^{2+} (Scheme 13) [225]. The one-electron reduction potential of TCNQ ($E^\circ_{\text{red}} = 0.19 \text{ V}$ vs. SCE) is therefore not affected by the presence of Mg^{2+} [225], whereas the one-electron oxidation potentials of BNAH ($E^\circ_{\text{ox}} = 0.57 \text{ V}$ vs. SCE) [222] in MeCN is significantly shifted to the positive direction by the complexation with Mg^{2+} (0.80 V vs. SCE) [226]. Thus, the significant decrease in the reactivity of BNAH by the complexation with Mg^{2+} is ascribed to a decrease in the electron donor ability as observed in photo-induced electron transfer from AcrH_2 to $[\text{Ru}(\text{bpy})_3]^{2+*}$ in the presence of HClO_4 (Figure 5), where protonated AcrH_2 cannot act as an electron donor [102].

When TCNQ is replaced by a weaker oxidant such as 2,6-dichloro-*p*-benzoquinone, the Mg^{2+} ion shows both retarding and accelerating effects on the hydride transfer reaction depending on the Mg^{2+} concentration, as shown in Figure 10, where the observed second-order rate constant (k_{obs}) decreases sharply from the value in the absence of Mg^{2+} ($7.5 \times 10 \text{ M}^{-1} \text{ s}^{-1}$) with an increase in $[\text{Mg}^{2+}]$ at low concentrations ($\ll 0.10 \text{ M}$), while the k_{obs} value increases at higher concentrations ($> 0.10 \text{ M}$) [226]. Such decelerating and accelerating effects of Mg^{2+} on the hydride transfer rate can be well understood based on Scheme 14, in which Mg^{2+} -catalyzed electron transfer from BNAH to X–Q (X = 2,6-Cl₂) is the rate-determining step in

Figure 10. Plot of k_{obs} vs. $[\text{Mg}(\text{ClO}_4)_2]$ for the hydride transfer reaction from BNAH to 2,6- Cl_2Q in the presence of $\text{Mg}(\text{ClO}_4)_2$ in MeCN at 298 K [226].

Scheme 14.

the overall hydride transfer reactions in the absence and presence of Mg^{2+} [226]. The electron transfer from BNAH to X-Q is accelerated by the complexation of Mg^{2+} with X-Q⁻, while the complexation of Mg^{2+} with BNAH retards the electron transfer. The initial sharp decrease in the rate constant from the value in the absence of Mg^{2+} to those at low concentrations ($\ll 0.10$ M) is ascribed to the complexation of Mg^{2+} with BNAH. With an increase in the Mg^{2+} concentration, not only one Mg^{2+} but also two Mg^{2+} ions can form the complex with Q⁻ (Eqs. 11 and 12), resulting in a second-order dependence of k_{obs} with respect to $[\text{Mg}^{2+}]$ at high Mg^{2+} concentrations as shown in Figures 10 and 7. In this region, the positive shift of the E°_{red} value of the quinone is larger than the corresponding positive shift

Figure 11. Plot of $\log k_{\text{obs}}$ for the hydride transfer reactions from BNAH to *p*-benzoquinone derivatives in the absence (○) and presence of Mg^{2+} [0.10 M (●), 1.6 M (△)] vs. the free energy change of electron transfer in the absence of Mg^{2+} ($\Delta G^\circ_{\text{et}}$) and in the presence of Mg^{2+} [$\Delta G_{\text{et}}(\text{Mg}^{2+})$] [226].

of BNAH (0.18 V), when the k_{obs} value increases with increasing $[\text{Mg}^{2+}]$ (Figure 6) [226].

The k_{obs} value should be correlated with the free energy change of electron transfer from BNAH to X–Q, which varies depending on X–Q and the Mg^{2+} concentration. The free energy change of electron transfer in the absence of Mg^{2+} ($\Delta G^\circ_{\text{et}}$) and that in the presence of Mg^{2+} [$\Delta G_{\text{et}}(\text{Mg}^{2+})$] are obtained from the E°_{ox} values of BNAH and the E_{red} values of *p*-benzoquinone derivatives in the presence of various concentrations of Mg^{2+} , which have been determined by the analysis of the cyclic voltammograms at various sweep rates [226]. Figure 11 shows plots of the $\log k_{\text{obs}}$ values in the absence and the presence of Mg^{2+} vs. $\Delta G^\circ_{\text{et}}$ and $\Delta G_{\text{et}}(\text{Mg}^{2+})$ [226]. The remarkable single and unified correlation in the absence and presence of Mg^{2+} in Figure 11 demonstrates clearly that the retarding and accelerating effects of Mg^{2+} on the rate constants of the overall hydride transfer reactions can be ascribed to the effects on the rate-determining electron transfer step in Scheme 14. The electron transfer step is followed by a proton transfer from $\text{BNAH}^{+\bullet}$ to $\text{Q}^{\bullet-}-\text{Mg}^{2+}$, and the subsequent electron transfer from BNA^\bullet to $\text{QH}^\bullet-\text{Mg}^{2+}$ may occur efficiently, judging from the largely negative oxidation potential of BNA^\bullet (–1.1 V vs. SCE) [222]. The observed primary kinetic isotope effects $k_{\text{H}}/k_{\text{D}}$ are well interpreted as those on the proton transfer step [226].

It is important to emphasize that three different types of reactions, i.e., electron transfer from (TPP)Co to Q (Eq. 13), Diels–Alder reaction of anthracenes with Q (Scheme 12) and hydride transfer from BNAH to Q (Scheme 14), have the common rate-determining step of Mg^{2+} -catalyzed electron transfer from these electron donors to Q. In each case, the relative catalytic dependence of k_{obs} on $[\text{Mg}^{2+}]$ is the same as indicated by Eq. 14, irrespective of different electron donors. The nucleophilic addition of a β,β -dimethyl-substituted ketene silyl acetal such as $\text{Me}_2\text{C}=\text{C}(\text{OMe})\text{OSiMe}_3$ is also catalyzed by Mg^{2+} in MeCN [227, 228]. No reaction takes

Scheme 15.

place between $\text{Me}_2\text{C}=\text{C}(\text{OMe})\text{OSiMe}_3$ and Q without Mg^{2+} in MeCN [227, 228]. The catalytic dependence of k_{obs} on $[\text{Mg}^{2+}]$ to Q has been shown to be the same as that for the Mg^{2+} -catalyzed electron transfer from (TPP)Co to Q (Eq. 14), changing from first- to second-order in $[\text{Mg}^{2+}]$ under the conditions that $\text{Q}^{\cdot-}$ forms the 1:2 complex with Mg^{2+} (Eq. 12). The β -methyl-substitution of ketene silyl acetals results in a significant increase in the electron donor ability to be becoming more susceptible to electron transfer oxidation than the less substituted counterparts [229–231]. The catalytic mechanism is shown in Scheme 15.

Electron transfer from $\text{Me}_2\text{C}=\text{C}(\text{OMe})\text{OSiMe}_3$ to Q is made possible by the strong interaction between $\text{Q}^{\cdot-}$ and Mg^{2+} (or 2Mg^{2+}) to produce the radical ion pair. Since the spin of the ketene silyl acetal radical cation is mainly localized on the terminal carbon atom [229], the carbon–oxygen bond is formed before the cleavage of the Si–O bond to yield the adduct (Scheme 15). This contrasts with the 1,2-addition of nonsubstituted ketene silyl acetal $[\text{H}_2\text{C}=\text{C}(\text{OEt})\text{OSiEt}_3]$ via nucleophilic attack to the positively charged carbonyl carbon of the quinone rather than via an alternative electron transfer pathway [228].

Hydride transfer from 1,5-dihydroflavin-2',3',4',5'-tetraacetate anion (FIH^-) to O_2 is also catalyzed by the presence of Mg^{2+} in acetonitrile [137]. The reduction of oxygen by the 1,5-dihydroflavin anion is known to be a key step in biological oxidation involving flavoproteins [80, 81]. An electron transfer mechanism has often been proposed for the reaction of 1,5-dihydroflavin with oxygen, since direct one-step reaction to give a covalent bond is spin-forbidden [232–234]. However, the facile follow-up reaction to give the covalent flavin 4a-hydroperoxide following the possible electron transfer has precluded the direct detection of the radical ion pair [232, 233]. In such a case, the comparison of the catalytic effects of Mg^{2+} on the hydride transfer reaction with that of electron transfer reduction of oxygen provides valuable insight into the viability of the electron transfer mechanism (see below).

The observed pseudo-first-order rate constant (k_{obs}) of the Mg^{2+} -catalyzed hydride transfer from FIH^- to O_2 increases linearly with increase in $[\text{Mg}(\text{ClO}_4)_2]$, as shown in Figure 12 [137]. There is an intercept which is much larger than the k_{obs}

Figure 12. Plot of k_{obs} vs. $[\text{Mg}(\text{ClO}_4)_2]$ for reduction of O_2 ($1.3 \times 10^{-3} \text{ M}$) by FlH^- ($1.2 \times 10^{-4} \text{ M}$) in the presence of $\text{Mg}(\text{ClO}_4)_2$ in MeCN at 298 K [137].

value in the absence of Mg^{2+} . Such first-order dependence of k_{obs} on $[\text{Mg}^{2+}]$ with an intercept is apparently different from first- and second-order dependences on $[\text{Mg}^{2+}]$ observed in the Mg^{2+} -catalyzed electron transfer from $[\text{Fe}(\text{Me}_5\text{C}_5)_2]$ to O_2 due to the 1:1 and 1:2 complexes formed between $\text{O}_2^{\cdot-}$ and Mg^{2+} at low and high Mg^{2+} concentrations (Eqs. 16 and 17), respectively. Such a difference in dependence of k_{obs} on $[\text{Mg}^{2+}]$ can be well interpreted by the complex formation between FlH^- and Mg^{2+} [137], as shown in Scheme 16 [137]. Flavins themselves are known to form complexes with Mg^{2+} in acetonitrile [235]. The reduced flavin anion FlH^- has also been reported to form the complex with Mg^{2+} [236]. Since the Mg^{2+} complex of FlH^- is a much weaker one-electron donor than free FlH^- , only free FlH^- which is in equilibrium with $\text{FlH}^- - \text{Mg}^{2+}$ can undergo the Mg^{2+} -catalyzed electron transfer reaction with O_2 to give a radical pair ($\text{FlH}^{\cdot} \text{O}_2^{\cdot-} - 2\text{Mg}^{2+}$). Since the spin density of FlH^{\cdot} is greater at the C-4a position (0.30) than those at the other carbons, the radical coupling between FlH^{\cdot} and $\text{O}_2^{\cdot-} - 2\text{Mg}^{2+}$ occurs selectively at the C-4a position to give flavin 4a-hydroperoxide which decomposes to Fl and hydrogen peroxide (Scheme 16) [137].

According to Scheme 16, the dependence of k_{obs} on $[\text{Mg}^{2+}]$ is given by Eq. 22:

$$k_{\text{obs}} = k'_0 K_1 (1 + K_2 [\text{Mg}^{2+}]) / K_0 \quad (22)$$

where k'_0 is the rate constant in the absence of Mg^{2+} , K_0 is the formation constant of $\text{FlH}^- - \text{Mg}^{2+}$ and K_1 and K_2 are the formation constants of $\text{O}_2^{\cdot-} - \text{Mg}^{2+}$ and $\text{O}_2^{\cdot-} - 2\text{Mg}^{2+}$, respectively ($K_1 [\text{Mg}^{2+}] \gg 1$) [137]. The dependence of k_{obs} on $[\text{Mg}^{2+}]$ in Figure 12 agrees with Eq. 22. Thus, from the intercept and slope the K_2 value is obtained as $3.4 \pm 0.3 \text{ M}^{-1}$, which agrees well with the K_2 value ($3.2 \pm 0.3 \text{ M}^{-1}$) obtained independently from Mg^{2+} -catalyzed electron transfer from $\text{Fe}(\text{C}_5\text{Me}_5)_2$ to

Scheme 16.

O_2 (Eq. 15) [137]. Such an agreement strongly indicates that Mg^{2+} -catalyzed electron transfer from FIH^- to O_2 is the rate-determining step for the hydride transfer from FIH^- to O_2 in the presence of Mg^{2+} (Scheme 16).

Metal ion catalysis is also effective for the reoxidation of reduced PQQ (pyrroloquinolinequinone) coenzyme by O_2 [237]. This coenzyme is the redox center of methanol dehydrogenases (MDH) that catalyze the oxidation of methanol to formaldehyde [238, 239]. The crystal structure of MDH from methylotrophic bacteria has shown that there is one calcium ion strongly bound to PQQ through its C-5 carboxylate group in the enzyme active site [240–243]. In this context, the oxidation of methanol to formaldehyde by the trimethyl ester of PQQ (PQQTME) has been shown to be catalyzed by Ca^{2+} [244]. The strong binding of Ca^{2+} to the pyridine nitrogen of $\text{PQQTME}^{\bullet-}$ is shown by the change in the hyperfine structure of the ESR spectrum due to the complexation [245]. This results in a 0.57 V positive shift in the one-electron reduction potential of PQQTME, indicating the enhancement of the oxidation power of PQQTME by a strong interaction between Ca^{2+} and $\text{PQQTME}^{\bullet-}$ [245]. The reduced PQQ also forms the Ca^{2+} complex, which is oxidized by O_2 via Ca^{2+} -catalyzed electron transfer from $\text{PQQTMEH}_2\text{--Ca}^{2+}$ to O_2 as shown in Scheme 17 [237].

Monovalent metal cations also influence the redox reactivity of tryptophan tryptophylquinone (TTQ) coenzyme in the amine oxidation and the subsequent electron transfer to the biological electron acceptor proteins such as amicyanin [246–251].

Scheme 17.

TTQ model compounds [252, 253] have been shown to form complexes with an alkali metal ion such as Li^+ (Eq. 23):

which can oxidize benzylamine in anhydrous MeCN, although no reaction takes place in the absence of Li^+ [254].

Hydride transfer via Brønsted acid-catalyzed electron transfer

Brønsted acid catalysis in electron transfer described in Section 1.3.1 has also been effective for redox reactions via the electron transfer step. As shown in the case of metal ion-catalyzed hydride transfer reactions (see above), hydride transfer reactions from an NADH analogue to *p*-benzoquinones also proceed via Brønsted acid-catalyzed electron transfer [255, 256]. Since NADH and ordinary NADH model compounds are subjected to the acid-catalyzed hydration [98, 257, 258], an acid-stable NADH model compound, 10-methyl-9,10-dihydroacridine (AcrH_2), was used as a hydride donor to *p*-benzoquinone (Eq. 24):

Figure 13 shows the pH dependence of the observed second-order rate constants ($\log k_{\text{obs}}$) for the hydride transfer from AcrH₂ to a series of hydride acceptors in H₂O-EtOH (5:1 v/v) at 298 K [256]. The $\log k_{\text{obs}}$ value of each Q in Figure 13 exhibits variation with pH in agreement with the pH dependence of $\log k_{\text{et}}$ of electron transfer from *cis*-[Et₂Co(bpy)₂]⁺ to Q in Figure 3. The $\log k_{\text{obs}}$ value of each Q is independent of pH in the region of pH > p*K*_{a1}, but increases with decreasing pH in the region pH < p*K*_{a1}. The p*K*_{a1} values thus determined for various *p*-benzoquinone derivatives agree well with the literature values [75]. In the case of 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ), the $\log k_{\text{obs}}$ value is independent of pH (Figure 13), since no protonation of TCNQ^{•−} has occurred in this pH region [256]. In general, the easier the reduction of a substrate, the more difficult is the protonation of the reduced species.

The kinetic deuterium isotope effects ($k_{\text{H}}/k_{\text{D}}$) are observed in the Brønsted acid-catalyzed hydride transfer reactions from AcrH₂ to the hydride acceptors (A) [259]. The pH dependence of the observed kinetic deuterium isotope effects ($k_{\text{H}}/k_{\text{D}}$) in-

Scheme 18.

indicates that hydrogen is transferred from AcrH_2^{2+} to AH^* following the initial electron transfer from AcrH_2 to A , as shown in Scheme 18 [259].

In biological redox systems, acid catalysis operates in a hydrophobic environment where the acid strength may be enhanced significantly as compared with that in an aqueous solution. Thus, in the model system, the use of an aprotic solvent may be essential to achieve a high activity of acid catalysis. The enormous enhancement of the rate of electron transfer reduction of carbonyl compounds by acid catalysis in MeCN (Figure 4) is expected to cause a significant decrease in the activation barrier for the two-electron reduction as well, since the subsequent reduction by hydrogen (equivalent to one electron and one proton) following the initial electron transfer is usually highly exergonic. In fact, the two-electron reduction of acetaldehyde, which is the most important substrate with regard to the physiological significance of ethanol metabolism and ethanol fermentation [260], by AcrH_2 is made possible in the presence of HClO_4 in acetonitrile [261]. When AcrH_2 is replaced by the 9,9'-dideuterated compound, 9,9'-[$^2\text{H}_2$]-9,10-dihydro-10-methylacridine (AcrD_2), deuterium is introduced to ethanol (Eq. 25) [261]:

Other aliphatic and aromatic ketones and aldehydes can also be reduced by AcrH_2 in the presence of HClO_4 in acetonitrile at 333 K [86, 261].

When the $\log k_{\text{obs}}$ values of the acid-catalyzed reduction of aliphatic aldehydes and ketones by AcrH_2 in the presence of HClO_4 and the $\log k_{\text{et}}$ values of acid-catalyzed photoinduced electron transfer from $[\text{Ru}(\text{bpy})_3]^{2+*}$ to the same carbonyl compounds (cf. Eq. 8) are compared, there exists an excellent linear correlation between $\log k_{\text{obs}}$ and $\log k_{\text{et}}$ as shown in Figure 14 [261]. The kinetic deuterium isotope effects ($k_{\text{H}}/k_{\text{D}}$) for the acid-catalyzed reduction of aliphatic aldehydes and ketones are uniformly small. For example, the $k_{\text{H}}/k_{\text{D}}$ values of acetaldehyde and pivalaldehyde are 1.4 and 1.0, respectively [261]. Similar linear correlations between k_{obs} and k_{et} are also obtained for other aromatic carbonyl compounds [86, 89]. These correlations strongly indicate that the rate-determining step for the hydride transfer reactions in the presence of HClO_4 is the H^+ -catalyzed electron transfer

Figure 14. Plot of $\log k_{\text{obs}}$ for the acid-catalyzed reduction of aldehydes and ketones by AcrH_2 in the presence of HClO_4 (2.7×10^{-2} M) in MeCN at 333 K vs. $\log k_{\text{et}}$ for the acid-catalyzed electron transfer from $[\text{Ru}(\text{bpy})_3]^{2+*}$ to the same series of substrates in the presence of HClO_4 (2.0 M) at 298 K. Numbers refer to the aldehydes and ketones (1, acetaldehyde; 2, propionaldehyde; 3, butyraldehyde; 4, isovaleraldehyde; 5, isobutyraldehyde; 6, pivalaldehyde; 7, acetone; 8, fluoroacetone; 9, cyclohexanone; 10, pyruvic acid) [261].

from AcrH_2 to the carbonyl compounds. Similarly, hydride transfer reactions from AcrH_2 to O_2 [90, 91], NO_2^- [92], nitrobenzene derivatives [93, 94], nitrosobenzene derivatives [93, 94] and sulfoxides [95, 96] proceed via H^+ -catalyzed electron transfer from AcrH_2 to these hydride acceptors.

Alkylsilanes, which are relatively stable against strong acids compared with other metal hydrides, have frequently been used as effective hydride donors for the acid-catalyzed reduction of carbonyl compounds [262, 263]. Although triethylsilane shows no reactivity toward carbonyl compounds in acetonitrile, the carbonyl compounds are readily reduced by Et_3SiH in the presence of HClO_4 to yield the corresponding alcohol together with a minor amount of the corresponding ether [264, 265]. In contrast with the case of the acid-catalyzed reduction of carbonyl compounds by AcrH_2 , comparison of the k_{obs} values of Et_3SiH and the k_{et} values of $[\text{Ru}(\text{bpy})_3]^{2+*}$ revealed no apparent parallel relation in the reactivities of carbonyl compounds. Since the one-electron oxidation potential (E°_{ox}) of Et_3SiH is higher than 2.3 V (vs. SCE) [265], that is significantly higher than the E°_{ox} value of AcrH_2 (0.81 V vs. SCE) [266], there is no chance of Et_3SiH acting as an electron donor in the acid-catalyzed reduction of carbonyl compounds. The reactivity of carbonyl compounds in the acid-catalyzed reduction by Et_3SiH is determined mainly by the protonation ability of the carbonyl compounds, while that in the acid-catalyzed electron transfer is determined by two-reverse effects, i.e., the proton- and electron-acceptor abilities [265].

Acid catalysis in overall *catalytic* cycle

An acid-catalyzed electron transfer reaction can be combined with other reactions to construct an overall *catalytic* reaction, where catalysis in an overall reaction is

Scheme 19.

written in italics in order to distinguish it from catalysis in electron transfer. For example, an acid-catalyzed electron transfer from $cis\text{-}[\text{R}_2\text{Co}(\text{bpy})_2]^+$ ($\text{R} = \text{Me}, \text{Et}$) to FIH^+ (Eq. 7) is combined with an acid-catalyzed oxidation of FIH_2 by O_2 as shown in Scheme 19 [267, 268]. The overall reaction is the *FI-catalyzed* oxidative coupling of alkyl ligands of $cis\text{-}[\text{R}_2\text{Co}(\text{bpy})_2]^+$ ($\text{R} = \text{Me}, \text{Et}$) by O_2 in the presence of HClO_4 in MeCN to yield R-R , $[\text{Co}(\text{bpy})_2]^{3+}$ and H_2O_2 [268]. The *catalytic* cycle is started by an H^+ -catalyzed electron transfer from $cis\text{-}[\text{R}_2\text{Co}(\text{bpy})_2]^+$ to FI. This is followed by the facile reductive elimination of the alkyl ligands of $cis\text{-}[\text{R}_2\text{Co}(\text{bpy})_2]^{2+}$ to yield the coupling product R-R [84]. Then an H^+ -catalyzed electron transfer from the resulting cobalt(II) complex to FIH_2^{**+} occurs to give $[\text{Co}(\text{bpy})_2]^{3+}$ and a protonated dihydroflavin FIH_3^+ . The FIH_3^+ is oxidized by O_2 to regenerate the oxidized protonated form (FIH^+) via H^+ -catalyzed electron transfer from FIH_3^+ to O_2 , accompanied by the formation of H_2O_2 [268]. Thus, each step in the *catalytic* cycle is catalyzed by an acid. Other redox coenzymes such as lumazine and aminopterine can also act as *catalysts* in the presence of an acid [268]. In the absence of a coenzyme analogue, the cobalt-carbon bond of $cis\text{-}[\text{R}_2\text{Co}(\text{bpy})_2]^+$ in both the absence and presence of O_2 is cleaved by the electrophilic attack of proton to yield $[\text{RCo}(\text{bpy})_2]^{2+}$ and RH [268]. The rates of FIH^+ -catalyzed oxygenation of $cis\text{-}[\text{R}_2\text{Co}(\text{bpy})_2]^+$ increase linearly with increasing concentration of both HClO_4 and FI [268].

The product in the coenzyme-catalyzed oxidation of $cis\text{-}[\text{R}_2\text{Co}(\text{bpy})_2]^+$ by O_2 in the case of $\text{R} = \text{PhCH}_2$ is drastically changed from R-R in the case of $\text{R} = \text{Me}$ and Et (Scheme 19) to the oxygenated product PhCH_2OOH as shown in Scheme 20 [268]. The initial acid-catalyzed electron transfer from $cis\text{-}[(\text{PhCH}_2)_2\text{Co}(\text{bpy})_2]^+$ to FIH^+ occurs to give $cis\text{-}[(\text{PhCH}_2)_2\text{Co}(\text{bpy})_2]^{2+}$ and FIH_2^{**+} . The cobalt-benzyl bond of $cis\text{-}[(\text{PhCH}_2)_2\text{Co}(\text{bpy})_2]^{2+}$ is cleaved in a stepwise manner [79], and the benzyl radical formed is stable enough to be trapped by O_2 to give benzylperoxyl radical ($\text{PhCH}_2\text{OO}^\bullet$), which is reduced by hydrogen transfer from FIH_2^{**+} to yield benzyl

Scheme 20.

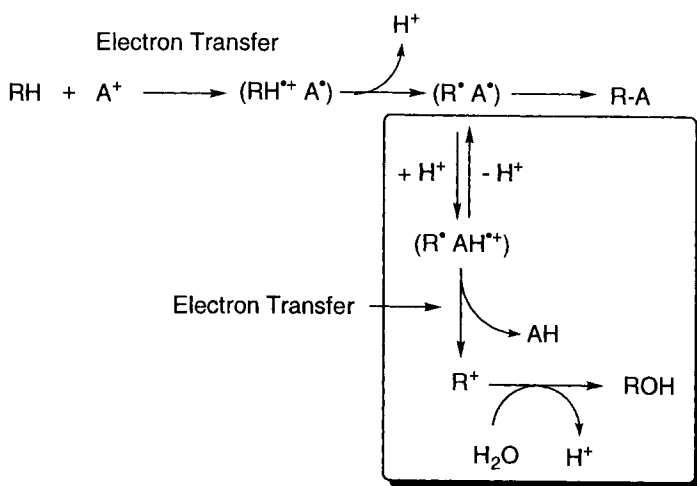

hydroperoxide, accompanied by regeneration of FIH^+ (Scheme 20). The benzyl hydroperoxide decomposes to yield the final oxygenated product, benzaldehyde [269].

In the absence of O_2 , the benzyl radical reacts with $[PhCH_2Co(bpy)_2]^{2+}$ in the cage to yield the coupling product, $PhCH_2CH_2Ph$ [79]. In the case of $cis-[R_2Co(bpy)_2]^+$ ($R = Me, Et$) also, the cleavage of the $Co-R$ bond in $cis-[R_2Co(bpy)_2]^{2+}$ may occur in a stepwise manner. However, the reaction of R^{\bullet} with $[RCo(bpy)_2]^{2+}$ may be so fast that R^{\bullet} cannot be trapped by oxygen and that only the net coupling of the alkyl ligands can occur to yield the coupling products even in the presence of O_2 . Thus, $cis-[(PhCH_2)_2Co(bpy)_2]^+$ is the least reactive in the electron transfer oxidation in the absence of O_2 because of the slow coupling process, but it becomes the most reactive in the FIH^+ -catalyzed oxidation by O_2 because of the facile trapping of the benzyl radical by O_2 [268]. Essentially the same reaction schemes (Schemes 19 and 20) are applied for other redox coenzyme analogues such as lumazine and aminopterine which act as catalysts in the oxidation of $cis-[R_2Co(bpy)_2]^+$ by O_2 in the presence of acid [268].

Metalloporphyrins can also act efficient *catalysts* in a variety of chemical and biological redox reactions. This area has been extensively studied and the catalytic functions of metalloporphyrins via electron transfer reactions have been reviewed Volume II, Part 2, Chapter 8 [270].

Change of reaction pathway by acid catalysis

As shown above, acid catalysis in an electron transfer process accelerates the rate of the overall redox reaction via the electron transfer without affecting the final products. However, there is a case when acid catalysis in an electron transfer process results in a drastic change of the products in the overall redox reactions (see below). In general, the radical cations of organic compounds ($RH^{+\bullet}$) are much stronger carbon acids in solution as compared with the parent compounds (RH) [271], and

Scheme 21.

thereby they undergo proton loss from an α -carbon to yield carbon radicals [38, 272–275]. On the other hand, there are some electron-rich radicals (A^\bullet) such as 10-methylacridinyl radical (AcrH^\bullet) which can act as a base to accept H^+ to produce the radical cation ($\text{AH}^{\bullet+}$) [222]. In the absence of a strong acid, an electron transfer from RH to A^+ may be followed by deprotonation of $\text{RH}^{\bullet+}$ to give the radical pair ($\text{R}^\bullet \text{A}^\bullet$) and the facile radical coupling yields the adduct (R-A) as shown in Scheme 21. In strongly acidic media, the reaction pathway is changed from the adduct formation to the two-electron oxidation of RH , since A^\bullet may be protonated to produce $\text{AH}^{\bullet+}$ which can oxidize R^\bullet to give R^+ and AH (Scheme 21).

In the absence of a strong acid, photoinduced electron transfer from RH (alkylbenzenes [276] and alkenes [277]) to the singlet excited state of AcrH^+ ($^1\text{AcrH}^{+\bullet}$) is reported to lead to formation of the alkylated or allylated adducts, 9-R-10-methyl-9,10-dihydroacridine (AcrHR). Photoinduced electron transfer from a variety of organometallic compounds (RM) also gave the same type of adduct, AcrHR [278–282]. In the presence of HClO_4 (1.2 M), however, the photooxygenation of ethylbenzene to 1-phenylethanol occurs as shown in Eq. 26:

where AcrH^+ is reduced to AcrH_2 instead of the adduct [283]. Judging from the one-electron oxidation potential of benzyl radical and analogues (R^\bullet), being more negative ($E^\circ_{\text{ox}} = 0.73, 0.37, 0.16$ and 0.35 V vs SCE for PhCH_2^\bullet , PhCHMe^\bullet , PhMe_2^\bullet and $\text{Ph}_2\text{CH}^\bullet$, respectively) [284, 285] than the reduction potential of $\text{AcrH}_2^{\bullet+}$ ($E^\circ_{\text{red}} = 0.81$ V vs. SCE) [266], the electron transfer from R^\bullet to $\text{AcrH}_2^{\bullet+}$ is highly exergonic and thereby it may proceed efficiently to yield AcrH_2 and R^+ (Scheme 21). The benzylic cation and analogues (R^+) may undergo the nucleophilic

addition of H_2O to yield the oxygenated product, i.e. the corresponding benzyl alcohol derivatives (ROH). In the case of the other alkylbenzenes such as cumene and diphenylmethane, the photoinduced hydride reduction of AcrH^+ to AcrH_2 occurs in the presence of HClO_4 , accompanied by the oxygenation of alkylbenzenes to the corresponding benzyl alcohol [283]. When the HClO_4 concentration is reduced from 1.2 to 0.10 M in the photochemical reaction of AcrH^+ with diphenylmethane, comparable amounts of AcrH_2 and AcrHCHPh_2 are obtained in the ratio of 59:41 [283]. Thus, acid catalysis in electron transfer from R^* to AcrH^* plays an essential role to alter the products in the presence of HClO_4 (Scheme 21), although it does not affect the overall efficiency of the photochemical reaction significantly.

1.3.5 Lewis Acid Catalysis in C–C bond Formation via Electron Transfer

Lewis acids generally activate carbonyl substrates through coordination for nucleophilic attack [286–289]. In some cases, however, Lewis acids have been reported to act as an electron acceptor rather than an acid when relatively strong electron donors are employed as nucleophiles [290–296]. As described earlier, the β -methyl substitution of ketene silyl acetals increases the electron density rendering the donor more susceptible to the electron transfer oxidation than the less substituted counterparts [229], while it also generally increases the steric hindrance of the reaction center, thereby reducing the reactivity of the nucleophilic attack toward electrophiles [228, 297, 298]. When β,β -dimethyl-substituted ketene silyl acetal such as $\text{Me}_2\text{C}=\text{C}(\text{OEt})\text{OSiEt}_3$ is employed as a nucleophile, an electron transfer from $\text{Me}_2\text{C}=\text{C}(\text{OEt})\text{OSiEt}_3$ to a Lewis acid such as SnCl_4 is suggested to initiate the catalytic cycle for Mukaiyama–Michael reaction of the ketene silyl acetal as shown in Scheme 22 [292]. The SnCl_4 anion radical formed in the electron transfer step spontaneously decomposes to $^*\text{SnCl}_3$ and Cl^- . The $^*\text{SnCl}_3$ radical then reacts with an α -enone in a 1,4-fashion to give a stannyl enolate radical which subsequently couples with the cation radical to give a stannyl enolate of the Michael adduct (Scheme 22). Transmetalation of this intermediate with in situ-formed trialkylsilyl chloride produces the corresponding silyl enol ether and regenerates SnCl_4 (Scheme 22). In this process, the close contact between sterically demanding reaction sites at an early stage is of no virtual importance. Thus, the crossover reaction of an equimolar mixture of $\text{Me}_2\text{C}=\text{C}(\text{OEt})\text{OSiEt}_3$ and $\text{H}_2\text{C}=\text{C}(\text{OEt})\text{OSiEt}_3$ with a hindered α -enone in the presence of a Lewis acid gave the adduct of $\text{Me}_2\text{C}=\text{C}(\text{OEt})\text{OSiEt}_3$ bearing contiguous quaternary carbon centers exclusively [292]. Such a preferred connection of more hindered carbons is characteristic of radical coupling via electron transfer in Scheme 22.

The competition reaction employing various types of ketene silyl acetals also reveals that those bearing more substituents at the β -position react preferentially over less substituted ones [296]. However, when ketene silyl acetals involve bulky siloxy and/or alkoxy group(s), less substituted compounds react preferentially as expected for a ubiquitous nucleophilic reaction depending on Lewis acids [296, 299, 300]. Enhanced preference for the more sterically demanding Michael adducts is obtained with $\text{Bu}_2\text{Sn}(\text{OTf})_2$, SnCl_4 and $\text{Et}_3\text{SiClO}_4$ in the former reaction while TiCl_4 gives the highest selectivity for the less sterically demanding products in the latter

Scheme 22.

case [296]. Thus, the change in the reactivity of ketene silyl acetals particularly with β -methyl substitution provides valuable insight into the electron transfer vs. nucleophilic process dichotomy [229, 296].

A similar electron transfer mechanism has been proposed for photosensitized electron transfer catalysis of the Mukaiyama-aldol reaction of aldehydes and ketones with enol silanes [301]. Photoinduced electron transfer from enol silanes to a monocationic N²¹,N²²-bridged porphyrin [302, 303] leads to the production of a trimethylsilyl radical which can act as a chain carrier for the aldol reaction under the irradiation of visible light [301].

1.3.6 Acid Catalysis in Photoinduced Electron Transfer

A first remarkable catalytic effect of metal ions (Mg²⁺ and Zn²⁺) was also found in photoinduced electron transfer reactions from various electron donors to flavin analogs (Fl in Scheme 5) [235, 304]. The increase in the oxidizing ability of the

singlet excited states of FI by the complex formation with Mg^{2+} or Zn^{2+} is evaluated quantitatively as the positive shifts of the one-electron reduction potential of the singlet excited state [$E^\circ(^1\text{FI}^*/\text{FI}^{\cdot-})$] [235]. The magnitude of the shift is approximately constant (0.33 ± 0.01 V) for different FI–metal ion complexes [235]. The complex formation with metal ions not only increases the oxidizing ability of the ground and excited states of FI but also stabilizes FI against irradiation of the visible light to prevent the photodegradation [235, 305]. For example, the quantum yield Φ_d of photodegradation of FI– Mg^{2+} complex in deaerated MeCN is 6.2×10^{-4} , which is negligibly small compared with that of a free flavin **1a** ($\Phi_d = 1.6 \times 10^{-2}$) [235]. Thus, irradiation of the absorption band of **1a**– Mg^{2+} complex makes it possible to oxidize benzyl alcohol derivatives to the corresponding benzaldehydes efficiently, while irradiation of a free flavin (**1a**) results in no dehydrogenation of *p*-methylbenzyl alcohol [305]. The reduced flavin– Mg^{2+} complex, $\text{FIH}_2\text{--Mg}^{2+}$, produced in the photooxidation of benzyl alcohols by FI– Mg^{2+} is readily oxidized by O_2 via Mg^{2+} -catalyzed electron transfer [137] to regenerate the oxidized form FI– Mg^{2+} [235]. In such a case, flavin–metal ion complexes act as efficient photocatalysts for the dehydrogenation of benzyl alcohol derivatives ($\text{X--C}_6\text{H}_4\text{CH}_2\text{OH}$) as shown in Scheme 23 [235]. Flavin– Mg^{2+} complexes can also catalyze photoinduced oxygenation of R_4Sn via photoinduced electron transfer from R_4Sn to $^1\text{FI}^*\text{--Mg}^{2+}$ in acetonitrile at 298 K [306].

Protonated flavin and pteridine analogues formed in the presence of perchloric acid can also function as efficient photocatalysts for the photooxidation of benzyl alcohols by oxygen via H^+ -catalyzed photoinduced electron transfer [307–309]. In contrast to the case of flavin and pteridine analogues, the triplet excited state of coenzyme pyrroloquinolinequinone (PQQ) by itself can oxidize benzyl alcohols to the corresponding aldehydes via photoinduced electron transfer, since the oxidizing ability of the triplet excited state of PQQ is much higher than that of flavin and pteridine analogues [310].

Complexation of metal ions with substrates not only can enhance the oxidizing ability of the substrate, but also can change the excited state property [52, 311].

Scheme 23.

Aromatic carbonyl compounds with lowest $n-\pi^*$ singlet states are generally non-fluorescent, possessing large $\pi-\pi^*$ triplet formation quantum yields (ca. 0.7) via fast intersystem crossing [312, 313]. However, irradiation of the absorption band due to Mg^{2+} complex of 1- or 2-naphthaldehyde formed in the presence of $\text{Mg}(\text{ClO}_4)_2$ causes strong fluorescence at 430–440 nm. Other metal ions such as Sc^{3+} are also effective for the change in the excited states of carbonyl compounds from the triplet to the singlet states by the complex formation [136]. The coordination of carbonyl compounds to metal ions results in an increased energy of the $n-\pi^*$ singlet state relative to the fluorescent $\pi-\pi^*$ singlet excited state as reported for similar change in the photophysical and photochemical properties of carbonyl compounds by the complex formation with Lewis acids [314–316].

The E°_{red} values (vs. SCE) of the singlet excited states of the Mg^{2+} -carbonyl complexes are determined by adaptation of the electron transfer free energy relationship for photoinduced electron transfer from various aromatic electron donors to the singlet excited states of the Mg^{2+} -carbonyl complexes in the presence of Mg^{2+} (1.0 M) in MeCN at 298 K [311]. A remarkable positive shift (1.2 V) in the E°_{red} values of the singlet excited states of the Mg^{2+} -carbonyl complexes is reported compared with those of the triplet excited states of free carbonyl compounds [311]. Such a large positive shift results in a significant increase in the reactivity of the Mg^{2+} complexes vs. free carbonyl compounds in the photoinduced electron transfer reactions [311]. A more substantial positive shift (1.5 V) in the E°_{red} values is observed when $\text{Mg}(\text{ClO}_4)_2$ is replaced by $\text{Sc}(\text{OTf})_3$ compared with those of the triplet excited states of free carbonyl compounds [136]. It should be noted that the 1.5 V positive shift corresponds to 10^{25} -fold acceleration of the electron transfer rate at 298 K. Such a remarkable enhancement of the reactivities of the excited states of carbonyl compounds by the complexation with metal ions (M^{n+}) makes it possible to perform the photochemical C–C bond formation reactions of carbonyl compounds with various electron donors ($\text{R}-\text{M}'$, e.g. R_4Sn and allyl- or benzylsilanes) via the metal ion-catalyzed photoinduced electron transfer which would otherwise be impossible to occur as shown in a general manner in Scheme 24 [136, 311].

Reactivities of protons toward excited organic and inorganic molecules have received much attention, since the acid–base equilibria in the excited states are changed drastically compared with those in the ground states [317–321]. The changes in the electron transfer properties such as the one-electron redox potentials and the reorganization energies of electron transfer due to the protonation of the excited states have yet to be determined in detail. A catalytic effect of Brønsted acids has been reported for an electron transfer in the triplet exciplex formed between the triplet excited state of methoxynaphthalene and the ground state of benzophenone [322, 323]. The rate of electron transfer increased with an increase in proton concentration [322, 323].

An intraexciplex electron transfer is also induced by hydrogen bonding of ROH (H_2O and methanol) to the carbonyl group of benzophenone (BP) in the triplet exciplex formed between the triplet excited state of *N,N*-dimethyl-1-naphthalene and the ground state of benzophenone as shown in Scheme 25 [324]. The driving force for the intraexciplex electron transfer is hydrogen bonding between $\text{BP}^{\bullet-}$ and ROH, which should result in a positive shift in the one-electron reduction potential of BP. It has also been reported that an intermolecular electron transfer takes place

Scheme 24.

Scheme 25.

upon excitation of a hydrogen-bonded donor–acceptor complex in the ground state and that the proton-coupled electron transfer was induced by the proton movement on the hydrogen bond [325–329]. Such a proton-coupled electron transfer has been suggested to play an important role in biological electron transfer rates [329–332], stimulating experimental [325–329, 334, 335] and theoretical studies [336–339]. In Scheme 25, however, no proton movement is involved when no kinetic isotope effect is observed in the hydrogen bonding-induced electron transfer [324].

1.4 Base Catalysis in Electron Transfer

As demonstrated above, the interaction of Brønsted and Lewis acids with an electron acceptor or the one-electron reduced species results in remarkable acceleration of the rate of electron transfer from an electron donor to the acceptor due to the

Scheme 26.

negative shift of the one-electron reduction potential of the acceptor (e.g., Eq. 4). Alternatively, the interaction of a base with an electron donor or the one-electron oxidized species should also result in acceleration of the rate of electron transfer from the electron donor to an acceptor due to the expected negative shift of the one-electron oxidation potential of the donor. Different types of base catalysis in electron transfer reactions are discussed below.

1.4.1 Base Catalysis by Deprotonation of Electron Donors

Various hydroquinone derivatives (X-QH₂) are readily deprotonated in the presence of 2 equiv. of Me₄N⁺OH⁻ in MeCN to produce the corresponding quinone dianion (X-Q²⁻) [340]. Although hydroquinones are weak electron donors, the corresponding quinone dianions, which are two-electron reduced species of quinones, are strong electron donors. Thus, stepwise electron transfer from 2 equiv. of 2,3-dimethylhydroquinone (Me₂QH₂) to [(TPP)Co]⁺ occurs in the presence of Me₄N⁺OH⁻ in MeCN to produce cobalt(I) tetraphenylporphyrin anion, [(TPP)Co]⁻, which can be further converted into the corresponding alkylcobalt(III) porphyrin, (TPP)Co(R), by an S_N2 reaction with alkyl halides (RX) as shown in Scheme 26 [341]. It should be noted that no electron transfer from Me₂QH₂ to [(TPP)Co]⁺ occurs in the absence of a base. The one-electron oxidation potential of Me₂Q²⁻ ($E^{\circ}_{\text{ox}} = -1.12$ V vs. SCE) is low enough to reduce (TPP)Co to [(TPP)Co]⁻ ($E^{\circ}_{\text{red}} = -0.85$ V vs. SCE) [341]. When a hydroquinone derivative with electron-withdrawing substituents such as tetrachlorohydroquinone or 2,3-dicyanohydroquinone is employed as an electron donor, no further reduction of (TPP)Co to [(TPP)Co]⁻ has been observed following the initial electron transfer from the dianion to [(TPP)Co]⁺ [340]. Whether the one- or two-electron reduction of [(TPP)Co]⁺ by X-QH₂ in the presence of 2 equiv. of Me₄N⁺OH⁻ occurs or not is determined by the difference in the E°_{ox} values of X-Q²⁻ or X-Q^{•-} and the E°_{red} values of (TPP)Co or [(TPP)Co]⁺ [340].

Similarly, the stepwise electron transfer from 2 equiv. of trimethylhydroquinone (Me₃QH₂) to C₆₀ occurs in the presence of Me₄N⁺OH⁻ in benzonitrile (PhCN) to produce C₆₀²⁻, which can be further converted into the corresponding dialkyl adduct (R₂C₆₀) by sequential electron transfer and S_N2 reactions with alkyl halides

Scheme 27.

(RX) as shown in Scheme 27 [342, 343]. The E°_{ox} value of Me_3Q^{2-} is also low enough to reduce $\text{C}_{60}^{\cdot -}$ to C_{60}^{2-} ($E^\circ_{\text{red}} = -0.87$ V vs. SCE) in PhCN [344]. The electrochemically generated C_{60}^{2-} and C_{70}^{2-} also undergo the alkylation reactions with alkyl halides to obtain dialkyl and tetraalkyl adducts of C_{60} [345–347].

The rates of oxidation of hydroquinone by polypyridyl-oxo-Ru complexes, $[(\text{bpy})_2(\text{Py})\text{Ru}^{\text{IV}}(\text{O})]^{2+}$ and $[(\text{bpy})_2(\text{Py})\text{Ru}^{\text{III}}(\text{OH})]^{2+}$ (bpy = 2,2'-bipyridine, Py = pyridine) in aqueous solution were reported to be pH dependent, and the rate enhancement in basic solution arises from the appearance of hydroquinone anion (QH^-) acting as a stronger electron donor than QH_2 [334]. In the case of $[(\text{bpy})_2(\text{Py})\text{Ru}^{\text{III}}(\text{OH})]^{2+}$, the rate enhancement is also observed in highly acidic solution where the protonated complex, $[(\text{bpy})_2(\text{Py})\text{Ru}^{\text{III}}(\text{OH}_2)]^{3+}$, acts as a stronger electron acceptor than $[(\text{bpy})_2(\text{Py})\text{Ru}^{\text{III}}(\text{OH})]^{2+}$ [334].

2-Nitropropane is also readily deprotonated in the presence of 1 equiv. of $\text{Me}_4\text{N}^+\text{OH}^-$ in MeCN to produce the tetramethylammonium salt of 2-nitropropane anion [348]. The electron donor ability of 2-nitropropane anion is reduced when the Me_4N^+ counter cation is replaced by Li^+ owing to the strong binding between 2-nitropropane anion and Li^+ compared with Me_4N^+ . This is indicated by the more positive one-electron oxidation potential of the Li^+ salt ($E^\circ_{\text{ox}} = 0.48$ V vs. SCE) than that of the Me_4N^+ salt ($E^\circ_{\text{ox}} = 0.10$ V vs. SCE) [348]. Nitroalkane anions produced by deprotonation of nitroalkanes are known to play an essential role in radical chain nucleophilic substitutions (Scheme 1) [24–32]. An addition–cyclization reaction of nitroalkanes with tricyclic *o*-quinones has been reported to occur in the presence of $\text{Me}_4\text{N}^+\text{OH}^-$ in MeCN via electron transfer in the charge-transfer complex formed between nitroalkane anions and the *o*-quinones, followed by C–O adduct formation and subsequent cyclization to afford the 1,3-dioxole derivatives as shown in Scheme 28 [349].

The anodic oxidation of RCOO^- produced by deprotonation of RCOOH occurs at about 2 V (vs. SCE), known as the Kolbe reaction, producing the radical coupling products of the alkyl groups of RCOO^- , R–R and CO_2 [350]. Since the one-electron reduction potential of the singlet excited state $^1\text{AcrH}^{+*}$ (2.3 V vs. SCE) [351] is positive enough to oxidize RCOO^- , photoinduced electron transfer from RCOOH (R = H, Me, Et, *i*-Pr, *t*-Bu, $\text{C}_{11}\text{H}_{23}$, $\text{C}_{15}\text{H}_{31}$) to $^1\text{AcrH}^{+*}$ occurs in the

Scheme 28.

Scheme 29.

presence of NaOH to give a singlet radical pair $^1(AcrH^{\bullet} RCOO^{\bullet})$, in which $RCOO^{\bullet}$ undergoes facile decarboxylation in competition with the back electron transfer to give the reactant pair as shown in Scheme 29 [352]. The resulting radical pair $^1(AcrH^{\bullet} R^{\bullet})$ undergoes facile radical coupling to yield 9,10-dihydro-9-alkyl-10-methylacridine (AcrHR) selectively [352].

As discussed earlier, there is no need to have an interaction of a base catalyst with an electron donor (D) as is the case of an acid catalysis (Scheme 2). The interaction

Scheme 30.

of a base with the oxidized state ($\text{D}^{*\bullet+}$) is sufficient to accelerate the rate of electron transfer from the electron donor to an acceptor. Such an example was reported for a base-catalyzed electron transfer from BNAH to tetracyanoethylene (TCNE) [353, 354]. Although there is no interaction between BNAH and pyridine, $\text{BNAH}^{*\bullet+}$ can be readily deprotonated by pyridine [222]. Since the one-electron oxidation potential of $\text{BNAH}^{*\bullet+}$ produced by deprotonation of BNAH ($E^\circ_{\text{ox}} = -1.08$ V vs. SCE) is much more negative than the one-electron reduction potential of TCNE ($E^\circ_{\text{red}} = 0.22$ V vs. SCE) [222], BNAH can reduce 2 equiv. of TCNE in the presence of pyridine as shown in Scheme 30 [354]. The observed second-order rate constant (k_{obs}) of the base-catalyzed electron transfer increases linearly with increasing the pyridine concentration [354].

The presence of a base is also essential for the efficient reductive dehalogenation of RX by BNAH via photoinduced electron transfer [355, 356]. Since the one-electron oxidation potential of the singlet excited state of BNAH ($^1\text{BNAH}^*$) is -3.1 V (vs. SCE) [351], which is more negative than the one-electron reduction potential of benzyl bromide (PhCH_2Br), photoinduced electron transfer from $^1\text{BNAH}^*$ to PhCH_2Br occurs efficiently with the diffusion-limited rate [356]. This fast process needs no base catalyst to accelerate the electron transfer rate further. However, the photoinduced electron transfer results in the formation of $\text{BNAH}^{*\bullet+}$, which is a strong acid to generate H^+ . Since BNAH is known to decompose efficiently via acid-catalyzed hydration [98, 257, 258], proton has to be removed in order to achieve the efficient photoreduction of PhCH_2Br by BNAH. As such the addition of pyridine (7.42×10^{-2} M) to the BNAH- PhCH_2Br system results in a significant increase in the product yield (toluene) of the photochemical reaction from 1.7 % in the absence of pyridine to 80 % [356, 357].

1.4.2 Base Catalysis via Formation of Base Adducts

Hydroxide ion (OH^-) in aprotic solvents has been reported to act as an electron donor in the one-electron reduction of quinones and other electron acceptors [358, 359]. However, the actual electron donor has been shown to be the quinone in the

Scheme 31.

presence of OH^- in MeCN and therefore no oxidized product of OH^- is formed [133]. When OH^- is added to *p*-benzoquinone (Q), the adduct anion can act as a strong electron donor toward Q as shown in Scheme 31 [133]. Electron transfer from the adduct anion to Q occurs accompanied by deprotonation to yield OH-substituted semiquinone radical anion and $Q^{\bullet -}$. The subsequent electron transfer from the OH-substituted semiquinone radical anion to $Q^{\bullet -}$ occurs rapidly to yield OH-substituted quinone and $Q^{\bullet -}$. Thus, one-electron substitution of Q by OH, which corresponds to the two-electron oxidation of Q, results in the one-electron reduction of 2 equiv. of Q to yield two $Q^{\bullet -}$. In consequence, the successive substitution of Q by OH finally results in the formation of 10-electron oxidized species, accompanied by the one-electron reduction of 10 equiv. of Q to yield 10 $Q^{\bullet -}$ as shown in Scheme 31 [133]. Thus, such a novel disproportionation of *p*-benzoquinone, in which the quinone itself acts as a 10-electron donor in the presence of OH^- , is responsible for the apparently quantitative formation of semiquinone radical anion.

Reactions of *p*-benzoquinone and its derivatives with alkoxide ions (RO^- ; R = H, Me, Et, *i*-Pr, $PhCH_2$) in MeCN also result in formation of the corresponding semiquinone radical anions accompanied by the formation of RO-substituted *p*-benzoquinones, which are the oxidized products of *p*-benzoquinones [360]. Detailed product and kinetic analyses of the reactions indicate that RO-adduct anion of *p*-benzoquinone is an actual electron donor and that RO^- is acting as a very strong base or nucleophile rather than a one-electron reductant in an aprotic solvent, such as MeCN [360]. Similarly, the reaction of C_{60} with methoxide anion (MeO^-) in benzonitrile ($PhCN$) results in the disproportionation of C_{60} to yield both $C_{60}^{\bullet -}$ and the methoxy adduct [360]. Spectroscopic and kinetic studies also indicate that a methoxy adduct anion of C_{60} is a real electron donor and that MeO^- is acting as a very strong base or nucleophile rather than an electron donor in $PhCN$ [360].

A weak base such as H_2O can accelerate the rate of electron transfer disproportionation of anthracene radical cation in MeCN by the interaction between anthracene dication produced in the electron transfer and H_2O [361]. The four-electron oxidation of 9-benzylanthracene ($PhCH_2An$) with more than 4 equiv. of

Scheme 32.

$[\text{Ru}(\text{bpy})_3]^{3+}$ proceeds via the rate-determining electron transfer disproportionation of $\text{PhCH}_2\text{An}^{\bullet+}$ to yield 10-benzyl-10-hydroxy-9(10H)-anthracenone as shown in Scheme 32 [361, 362]. The dihydroxy adduct of $\text{PhCH}_2\text{An}^{2+}$ produced in the H_2O -catalyzed electron transfer disproportionation of $\text{PhCH}_2\text{An}^{\bullet+}$ is further oxidized to 10-alkyl-10-hydroxy-9(10H)-anthracenone by 2 equiv. of $[\text{Ru}(\text{bpy})_3]^{3+}$ (Scheme 32) [362]. The observed second-order rate constant (k_{et}) for the second-order decay of $\text{PhCH}_2\text{An}^{\bullet+}$ due to the electron transfer disproportionation increases with an increase in $[\text{H}_2\text{O}]$ to exhibit a first-order dependence on $[\text{H}_2\text{O}]$ at low concentrations, changing to a second-order dependence at high concentrations [361]. There is no kinetic deuterium isotope effect of water for the decay of $\text{PhCH}_2\text{An}^{\bullet+}$ when H_2O is replaced by D_2O [361]. The first- and second-order dependence of k_{obs} of $\text{PhCH}_2\text{An}^{\bullet+}$ on $[\text{H}_2\text{O}]$ can be explained by the complex formation of $\text{PhCH}_2\text{An}^{2+}$ with one and two H_2O molecules as shown in Scheme 32 [361].

The complex formation of $\text{PhCH}_2\text{An}^{2+}$ and H_2O should result in a negative shift of the one-electron oxidation potential of $\text{PhCH}_2\text{An}^{\bullet+}$ (E_{ox}). The Nernst equation may be expressed as

$$E_{\text{ox}} = E_{\text{ox}}^{\circ} - (2.3RT/F) \log K_1[\text{H}_2\text{O}](1 + K_2[\text{H}_2\text{O}]) \quad (27)$$

where E_{ox}° is the one-electron oxidation potential of $\text{PhCH}_2\text{An}^{\bullet+}$ in the absence

of H_2O and K_1 and K_2 are the formation constants for the complex between $\text{PhCH}_2\text{An}^{2+}$ and one and two H_2O molecules, respectively ($K_1[\text{H}_2\text{O}] \gg 1$) [361]. From Eq. 27 is derived the dependence of the rate constant of electron transfer disproportionation (k_{et}) on $[\text{H}_2\text{O}]$ as given by Eq. 28:

$$k_{\text{et}} = k_0 k_{\text{et}0} (1 + K_1[\text{H}_2\text{O}] + K_1 K_2 [\text{H}_2\text{O}]^2) \quad (28)$$

where $k_{\text{et}0}$ is the rate constant in the absence of H_2O . The experimental observation agrees with the dependence of k_{et} on $[\text{H}_2\text{O}]$ in Eq. 28 [361]. The six-electron oxidation of anthracene to anthraquinone also occurs with $[\text{Ru}(\text{bpy})_3]^{3+}$ in MeCN via the H_2O -catalyzed electron transfer disproportionation of anthracene radical cation [361].

The deprotonation and addition of a base to thiazolium salts are combined to produce an acyl carbanion equivalent (an active aldehyde) [363, 364], which is known to play an essential role in catalysis of the thiamine diphosphate (ThDP) coenzyme [365, 366]. The active aldehyde in ThDP dependent enzymes has the ability to mediate an efficient electron transfer to various physiological electron acceptors, such as lipoamide in pyruvate dehydrogenase multienzyme complex [367], flavin adenine dinucleotide (FAD) in pyruvate oxidase [368] and Fe_4S_4 cluster in pyruvate-ferredoxin oxidoreductase [369].

The active aldehydes are derived from the reaction of 3-benzylthiazolium salts with *o*-tolualdehyde in the presence of DBU (1,8-diazabicyclo[5.4.0]undec-7-ene) via deprotonation of thiazolium salts, addition of the aldehyde and deprotonation of the adduct as shown in Scheme 33 [364]. The anionic form of active aldehydes in Scheme 33 is confirmed by the direct detection of the one-electron oxidized species with use of ESR [364]. From the linewidth variations of the ESR spectra of the oxidized active aldehyde radicals were determined the rate constants $[(5-7) \times 10^8 \text{ M}^{-1} \text{ s}^{-1}]$ and the corresponding small reorganization energies ($\lambda = 12-13 \text{ kcal mol}^{-1}$) of electron transfer exchange reactions between the active aldehyde and the radicals [370]. The one-electron oxidation potentials of the active aldehydes are nearly the same ($E^\circ_{\text{ox}} = -0.93$ to -0.98 V) irrespective of parent aldehydes [364]. The small reorganization energies and the highly negative oxidation potentials of the active aldehydes indicate the high reducing ability to mediate electron transfer to an electron acceptor. This has been confirmed by using tris(1,10-phenanthroline)cobalt(II) complex, $[\text{Co}(\text{phen})_3]^{2+}$ (phen = 1,10-phenanthroline), which is reduced by the active aldehydes to $[\text{Co}(\text{phen})_3]^+$ (Scheme 33) [364]. Thus, the active aldehydes are suitable for fast electron transfer systems where they can act as efficient electron transfer *catalysts* [364].

1.4.3 Control of Reorganization Energy by Base Catalysis

There are two factors to control the rate of electron transfer, i.e., the free energy change of electron transfer ($\Delta G^\circ_{\text{et}}$) and the reorganization energy of electron transfer (λ), as shown in Figure 2. When the λ values are relatively small in the electron transfer system as described so far, the main factor to accelerate the rates of

Scheme 33.

electron transfer by a catalyst is the change of redox potentials by the interaction of the products of electron transfer. When the λ value is large in an electron transfer system, a decrease in λ by the interaction with a catalyst would result in acceleration of the electron transfer rate. Such examples have been reported as described below [371, 372].

The electrochemical studies of (P)MnCl, where P represents either the dianion of tetraphenylporphyrin (TPP), which is planar, or of the dianion of dodecaphenylporphyrins (DPPX, X = H₂₀, Cl₁₂H₈, F₂₀), which are known to adopt a nonplanar conformation [373, 374], have shown that the Mn(III)/Mn(II) reduction is quasi-reversible [375], and that the separation between the cathodic and anodic peak potentials, $\Delta E_p = |E_{pc} - E_{pa}|$, increases in the order (TPP)MnCl < (DPPH)MnCl < (DPPCl₁₂)MnCl < (DPPF₂₀)MnCl [376, 377]. The large ΔE_p value (0.52 V) in the case of (DPPF₂₀)MnCl reduction is due to slow electron transfer kinetics, as has been reported for other (P)MnCl complexes [378]. The slow electron transfer reduction of (DPPX)MnCl was confirmed by determining the rate constant (k_{et}) of electron transfer from semiquinone radical anions (Q^{•-}) to each Mn(III) porphyrin (Scheme 34) [379]. The fit of the dependence of $\log k_{et}$ on the free energy change of

Scheme 34.

electron transfer ($\Delta G^\circ_{\text{et}}$) to the Marcus theory of adiabatic outer-sphere electron transfer [70] (Figure 15) indicates that the rate variations at a given $\Delta G^\circ_{\text{et}}$ value arise from the difference in the λ value given in Figure 15 and not from the non-adiabaticity [379].

The slow electron transfer reduction of $(\text{DPPH}_{20})\text{MnCl}$ can be accelerated significantly by axial coordination of a base, when the addition of a nitrogenous base such as pyridine (Py) to the five-coordinate complex gives the six-coordinate complex $[(\text{DPPH}_{20})\text{Mn}(\text{Py})_2]^+$ as shown in Figure 15 [371]. The reduction of $[(\text{DPPH}_{20})\text{Mn}(\text{Py})_2]^+$ occurs at $E^\circ_{\text{red}} = -0.41$ V vs. SCE, which is slightly more negative than the E°_{red} value (-0.36 V) of the five-coordinate complex, $(\text{DPPH}_{20})\text{MnCl}$ ($E^\circ_{\text{red}} = -0.36$ V) [371]. Such a small negative shift of E°_{red} by coordination of pyridine cannot account for the large acceleration in the rate of electron transfer for the six-coordinate complex as compared with the five-coordinate complex as shown by the arrows along the curve with a constant λ value in Figure 15. Thus, the acceleration in the rate of electron transfer upon axial coordination of pyridine results from a significant decrease in the reorganization energy associated with the electron-transfer reduction of $[(\text{DPPH}_{20})\text{Mn}(\text{Py})_2]^+$. This is shown by the vertical arrows in Figure 15, where the dependence of $\log k_{\text{et}}$ for the electron-transfer reduction of $[(\text{DPPH}_{20})\text{Mn}(\text{Py})_2]^+$, using a λ value of 30 kcal mol^{-1} , is given by the dashed line. The λ value becomes close to the value for the planar porphyrin [27 kcal mol^{-1} for $(\text{TPP})\text{MnCl}$] [371].

The addition of pyridine to the $(\text{OETPP})\text{Fe}(\text{C}_6\text{F}_5)-[\text{Fe}(4,7\text{-Me}_2\text{phen})_3]^{3+}$ system (OETPP = the dianion of 2,3,7,8,12,13,17,18-octaethyl-5,10,15,20-tetraphenylporphyrin) also results in a significant increase in the rate of electron transfer from $(\text{OETPP})\text{Fe}(\text{C}_6\text{F}_5)$ to $[\text{Fe}(4,7\text{-Me}_2\text{phen})_3]^{3+}$ [372]. The rate constant (k_{et}) of electron transfer of the six-coordinate complex $[(\text{OETPP})\text{Fe}(\text{C}_6\text{F}_5)(\text{Py})]$ in the presence of

Figure 15. Dependence of $\log k_{\text{et}}$ on $\Delta G^{\circ}_{\text{et}}$ for electron-transfer from semiquinone radical anions to (P)MnCl in deaerated MeCN at 298 K. Numbers refer to the system: 1, (DPPH₂₀)MnCl/Q^{•-}; 1', [(DPPH₂₀)Mn(py)₂]⁺/Q^{•-}; 2, (DPPH₂₀)MnCl/MeQ^{•-}; 2', [(DPPH₂₀)Mn(py)₂]⁺/MeQ^{•-}; 3, (DPPH₂₀)MnCl/2,6-Me₂Q^{•-}; 4, (DPPCl₁₂H₈)MnCl/Q^{•-}; 5, (DPPF₂₀)MnCl/ClQ^{•-}; 6, (DPPCl₁₂H₈)MnCl/MeQ^{•-}; 7, (DPPCl₁₂H₈)MnCl/2,6-Me₂Q^{•-}; 8, (DPPF₂₀)MnCl/Q^{•-}; 9, (DPPF₂₀)MnCl/Q^{•-}; 10, (DPPF₂₀)MnCl/Q^{•-}; 11, (TPP)MnCl/2,5-Cl₂Q^{•-}; 12, (TPP)MnCl/ClQ^{•-}; 13, (TPP)MnCl/Q^{•-} [371]. The solid and dashed lines were drawn based on the Marcus theory of electron transfer using the λ values shown.

pyridine ($3.4 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$) is much larger than the k_{et} value of the five-coordinate complex [(OETPP)Fe(C₆F₅)] ($6.7 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$) [372]. The one-electron oxidation potential is expected to be shifted in a negative direction by the axial ligand coordination of pyridine, when the electron transfer oxidation becomes energetically more favorable. However, the observed positive shift in the oxidation potential in pyridine compared with the observed potential in MeCN is only 0.09 V, which cannot account for the remarkable acceleration of the rate of electron transfer for the pyridine-coordinated complex compared with the non-coordinated complex [372]. Thus, the acceleration in the rate of electron transfer upon axial coordination of pyridine results from a significant decrease in the reorganization energy associated with the electron transfer oxidation of the six-coordinate complex [(OETPP)Fe(C₆F₅)(Py)] than that for the five-coordinate complex [(OETPP)Fe(C₆F₅)]. The sixth axial coordination of a base minimizes the structural change associated with the electron transfer, since the six-coordinate iron atom may remain in the plane of the rather rigid porphyrin ligand irrespective of the oxidation state.

The sixth axial coordination of a base (L) also affects the rate of metal–carbon bond cleavage via an intramolecular electron transfer from the σ -bonded axial ligand (R) to the metal center in [(TPP)Co(R)(L)]⁺ produced by the one-electron oxidation of (TPP)Co(R), which leads to R group migration from the metal to ni-

trogen in $[(\text{TPP})\text{Co}(\text{R})]^+$ [380]. The migration rate of $[(\text{TPP})\text{Co}(\text{Ph})(\text{L})]^+$ increases by 1–2 orders of magnitude with increase in the ligand $\text{p}K_{\text{a}}$ [380].

1.5 Conclusions and Future Prospects

As demonstrated in this chapter, both thermal and photoinduced electron transfer reactions are accelerated by appropriate third components acting as catalysts when the products of electron transfer have strong interactions with the catalysts. Such interactions between the catalysts and the products of electron transfer result in significant changes in the free energy of electron transfer and the reorganization energies associated with the electron transfer. The catalysis in electron transfer processes is particularly important for controlling the redox reactions in which the electron transfer processes are involved as the rate-determining steps followed by facile follow-up steps involving cleavage and formation of chemical bonds. Once the thermodynamic properties of the complexation of acids or bases have been obtained, one can predict the kinetic formulation on the catalytic activity. There still remains a wealth of important fundamental questions with regard to catalysis in electron transfer, which have been only partially explored in the past, and which certainly deserve much more detailed attention in future.

When one thinks about only two-electron reduction of a substrate (A), the reduction and protonation give nine species at different oxidation and protonation states as shown in Scheme 35. Each species can have an interaction with a metal complex ($\text{M}^{n+}-\text{L}$) and such an interaction can control each redox step. Moreover, the interaction between the ligand L and a substrate has the possibility of controlling not only the reactivity but also the stereoselectivity of the redox reaction. With regard to multi-electron reduction or oxidation of a substrate, the much more redox and protonated or deprotonated states should be considered for the interaction with metal complexes. The scope and the application of catalysis in electron transfer are thereby expected to expand much further in the near future.

Scheme 35.

Acknowledgments

The author is deeply indebted for the work of all collaborators, co-workers and talented students whose names are listed in the references in this chapter (in particular, Prof. K. M. Kadish, Prof. J. Otera, Prof. S. Itoh and Dr. T. Suenobu). The author acknowledges continuous support of his studies on electron transfer chemistry by a Grant-in-Aid from the Ministry of Education, Science, Culture and Sports, Japan. The author also thanks Assoc. Prof. H. Imahori for helpful discussions.

2 Redox Modulation by Molecular Recognition

Vincent M. Rotello

2.1 Introduction

The control of electron transfer processes through specific non-covalent interactions is a general phenomenon in biological systems. Enzymes containing redox-active organic molecules such as quinones [1], flavins [2], nicotinamides [3], and pterins [4] use specific enzyme–cofactor interactions to regulate the reactivity of the cofactor. Using hydrogen bonding, π -stacking and other electrostatic interactions, these enzymes exert powerful control over the redox behavior of the cofactor, selectively stabilizing specific oxidation and protonation states. Equally important to the proper function of redox enzymes are the more subtle consequences of enzyme–cofactor interactions, such as the control of molecular orbital distribution provided through enzyme–cofactor interactions. Finally, the protein matrix plays a crucial role in the regulation of both intra- and interprotein electron transfer pathways [5, 6]. Taken together, these modes of enzymatic regulation of redox events demonstrate that redox enzymes utilize molecular recognition to control all aspects of electron transfer processes.

Understanding the fundamental principles governing the interplay of redox processes and molecular recognition is invaluable both in the context of biochemistry as well as in the field of materials science [7], where complex biological systems can be used as prototypes for pragmatic devices [8, 9]. In this chapter, we will explore the role of noncovalent apoenzyme–cofactor interactions in controlling the redox processes of bioorganic cofactors [10, 11], including biochemical and structural studies of the parent biomolecular systems. Additionally, the application of supramolecular model systems [12] will be presented: through these model systems, the effects of hydrogen bonding, π -stacking and dipolar interactions on electron transfer processes can be decoupled in ways that are difficult or impossible to do within the complex biomolecular environment of the enzyme active site.

The role of enzyme–cofactor noncovalent interactions in controlling biological electron transfer processes can be divided into four key areas:

- 1) modulation of redox potentials;
- 2) control of molecular orbital geometries;
- 3) proton-coupled electron transfer processes;
- 4) electron transport through the protein matrix.

Each of these topics will be discussed in turn. Intra- and interprotein electron transport will not be discussed; they are covered in the contribution by Tollin in this volume.

2.2 Modulation of Redox Potentials by Noncovalent Interactions

The redox potentials of organic cofactors are directly responsible for controlling the equilibrium behavior of the corresponding cofactor-mediated electron transfer processes. The relative redox potentials of the cofactor and its redox partner are also intimately related to the rate of adiabatic electron transfer k_{ET} through the classical Marcus equation [13, 14], and nonadiabatic electron transfer through the semi-classical Marcus equation [15, 16]. The direct dependence of both the kinetics and thermodynamics of electron transfer processes on the cofactor redox potential makes the control of these potentials a key determinant of the activity of redox proteins.

Biochemical studies have shown that the redox potentials of bound cofactors are highly enzyme dependent. This variation in redox potentials arises from selective recognition of individual oxidation and protonation states of the cofactor by the apoenzyme. As an example, the one-electron reduction potential of the flavin cofactor (Figure 1a) in different flavoenzymes varies over a greater than 500 mV range, corresponding to a free energy differential ($\Delta\Delta G$) of over 12 kcal mol⁻¹ [17]. As the redox-active isoalloxazine nucleus is identical in all of these enzymes, this selective stabilization must arise from apoenzyme–cofactor noncovalent interactions. These interactions include charge–charge attraction and repulsion, as well as dipolar interactions such as hydrogen bonding. Additionally, recent studies (see below) have shown that less obvious multipolar interactions such as donor atom– π interactions and aromatic stacking can also strongly affect the redox properties of organic cofactors.

The fundamental origin of redox state-specific recognition can be seen from the changes in electrostatic potentials that occur when organic molecules undergo redox processes. Because noncovalent interactions such as hydrogen bonding, π -stacking and dipolar interactions are essentially electrostatic in nature [18], they are highly sensitive to changes in charge density distribution within the host–guest complex. The effect of redox state on charge distribution can be clearly observed in Figure 2, where we have calculated the changes in the electrostatic potential that occur when Q_{ox} is reduced to Q_{rad^-} , and Fl_{ox} is reduced to Fl_{rad^-} . These calculations were performed using the B3LYP-DFT hybrid DFT method on lumiflavin and ubiquinone Q_0 in both their oxidized and radical anion forms. This computational protocol has

Figure 1. Common redox and protonation states for (a) flavin and (b) quinone cofactors.

been shown to reproduce accurately experimentally measured parameters including energetics and spin-density distributions (see below) [19], therefore the electrostatic potentials derived from the wavefunction are expected to reflect accurately those of the molecular system.

From the calculations for flavin, we can see that the one-electron reduction of flavin increases the negative potential of carbonyl oxygens O(2) and O(4) substantially: for O(2) this potential increases from $-45 \text{ kcal mol}^{-1}$ (Fl_{ox}) to $-116 \text{ kcal mol}^{-1}$ (Fl_{rad}⁻) at the van der Waals radius. This increase in charge density makes these carbonyl oxygens more basic, hence they are much stronger hydrogen bond acceptors.

In addition to increasing charge density at the carbonyls, reduction of flavin to the anion radical converts the electron-deficient aromatic framework of Fl_{ox} into the electron-rich Fl_{rad}⁻. In the Fl_{ox} state, the positive electrostatic potential of the atoms on the central ring allows Fl_{ox} to form favorable π -stacking interactions with electron-rich aromatic systems and complementary electrostatic interactions with electron-rich functional groups. Fl_{rad}⁻, in contrast, possesses negative electrostatic

Figure 2. Electrostatic potentials derived from 6–31G* B3LYP-DFT//3–21G UHF calculations for Ubiquinone Q_0 in (a) the oxidized (Q_{ox}) and (b) the radical anion form (Q_{rad^-}) and lumiflavin in the oxidized (Fl_{ox}) and radical anion form (Fl_{rad^-}). Contour lines are at 60 kcal mol⁻¹ intervals.

potentials on the central and distal rings, making interactions with adjacent electron-rich systems highly unfavorable.

From the electrostatic potential maps, we can see how molecular recognition is related to the redox state of the guest/cofactor. The selective recognition of specific oxidation states is directly related to the potential required to shuttle between these oxidation states. This relationship can be quantified by the equation

$$\frac{K_a(\text{red})}{K_a(\text{ox})} = e^{(nF/RT)[E_{1/2}(\text{bound}) - E_{1/2}(\text{unbound})]} \quad (1)$$

where $K_a(\text{ox})$ and $K_a(\text{red})$ are the association constants in the oxidized and reduced form and $E_{1/2}(\text{unbound})$ and $E_{1/2}(\text{bound})$ are the standard reduction potentials in the unbound and receptor-bound forms. According to Eq. 1, enhanced binding [$K_a(\text{red})/K_a(\text{ox}) > 1$] inherently accompanies a positive shift in $E_{1/2}$ [$E_{1/2}(\text{bound}) - E_{1/2}(\text{unbound}) > 0$]. This direct correlation of redox and recognition is an important principle both in the understanding of biological systems and in the design of molecular devices.

2.2.1 Hydrogen Bonding

Hydrogen bonding is an efficient and specific recognition motif [20]. Depending on the directionality of the hydrogen bond donor–acceptor interaction, this interaction

Figure 3. Redox state-selective recognition of flavin.

can selectively stabilize or destabilize individual oxidation states, thereby modulating the redox potential between these states. An example of hydrogen bond modulation of redox processes can be seen with the flavin cofactor, where hydrogen bonding to O(2) and O(4) of flavin is expected to be more favorable in the Fl_{rad}^- than the Fl_{ox} redox state, because of the greater negative charge present in these positions in the radical anion (Figure 3). As a consequence, these interactions selectively stabilize the Fl_{rad}^- redox state, making the reduction of Fl_{ox} to Fl_{rad}^- less unfavorable. In contrast, hydrogen bonding to N(3)–H is stronger with Fl_{ox} than with Fl_{rad}^- , owing to the greater positive charge at this position in Fl_{ox} . Therefore, interactions at this position would make the reduction of Fl_{ox} to Fl_{rad}^- more unfavorable.

There are a number of recent examples of recognition-modulated redox processes in host–guest complexes that are consistent with the above predictions (Figure 4). Three-point hydrogen bonding of diacyldiaminopyridine derivatives to flavin was shown to make the reduction of Fl_{ox} to Fl_{rad}^- 155 mV ($3.6 \text{ kcal mol}^{-1}$) less negative (Figure 4a) [21]. These interactions are partially self-canceling: recent solvent studies have shown that hydrogen bonding to N(3)–H makes flavin reduction 76 mV ($1.8 \text{ kcal mol}^{-1}$) more negative [22]. This more negative potential is in line with the

Figure 4. Modulation by supramolecular hosts of the redox potential for the reduction of oxidized guests to the radical anion state in CH_2Cl_2 at ambient temperature.

Figure 5. Recognition and redox modulation of flavin by (a) diacyldiaminopyridine receptors and (b) diaminotriazine-based receptors [25].

above predictions regarding the effect of hydrogen bonding at this position. Subtraction of this compensating effect from the potential shifts observed with the diacyldiaminopyridine receptor–flavin complexes indicates that hydrogen bonding at O(2) and O(4) shifts the reduction potential to 231 mV ($5.4 \text{ kcal mol}^{-1}$) less negative. Subsequent experiments have shown similar shifts for the reduction of *o*-quinones to their radical anions using ureas as host molecules (Figure 4b) [23]. The degree of redox modulation can be increased through the use of multi-point interactions: large shifts in $E_{1/2}$ were also observed in the multidentate host–guest system developed by Yano et al. [24] (Figure 4c).

From the limited number of experimental studies available, it can be seen that hydrogen bonding can have a profound impact on the reduction potential of redox-active organic systems. Host molecules that donate hydrogen bonds to redox-active guests can make the reduction of these guests more than 100 mV less negative per hydrogen bond. Conversely, systems that accept hydrogen bonds from these guests make reduction substantially more difficult. These results are obviously preliminary; as an example, diacyldiaminopyridines bind flavins with the same affinity that diaminotriazines do (Figure 5). The effects of these two different classes of receptors on flavin reduction potentials, however, are different: the diacyldiaminopyridine receptors make the flavin reduction potential less negative, whereas the diaminotriazine receptors have relatively little effect. Clearly, careful parametric study of these host–guest complexes will be required to understand fully the structure–function relationship in these systems.

An important caveat in the design of redox-active host molecules is that the recognition element apparently needs to be a direct part of the redox-active skeleton: recent studies of uracils attached to tetrathiafulvenes (TTF) [26] and amides attached to ferrocenes [27] have demonstrated much weaker (~ 15 – 20 mV per hydrogen bond) effects of recognition on redox processes. The weakness of this modulation is surprising, since there are examples of similar systems where simple substituent effects on aromatic units attached to ureas [28] and diaminotriazines [29] have had much larger effects on hydrogen bonding than those seen in the above TTF and ferrocene systems. This lack of redox modulation is in spite of

Figure 6. Flavin binding site of the flavodoxin isolated from *Desulfovibrio vulgaris* [36].

the fact that a far larger change in electron density of the system is expected in the systems undergoing redox processes.

2.2.2 Aromatic Stacking

Aromatic stacking interactions [30, 31] are a prominent feature in recognition-modulated redox processes. In biological systems, stacking of π -electron-deficient cofactors such as flavins and quinones with electron-rich side-chain residues and substrates strongly modulates the redox potential of the cofactor. This stacking motif has also seen widespread application in the creation of molecular shuttles, where redox-selective recognition has been used to drive the shuttling action [32, 33].

In biological systems, the most extensively studied examples of stacking-modulated redox processes are the flavodoxins, which are electron transferases isolated from microbial sources [34]. In these enzymes, mutation of aromatic residues near the flavin binding site (Figure 6) has been shown to modulate the reduction potential of the $\text{Fl}_{\text{rad}}\text{H}/\text{Fl}_{\text{red}}\text{H}^-$ couple 140 mV less negative [35]. The modulation provided by the tyrosine residue arises from redox-state specific interactions: reduction of the relatively electron-poor $\text{Fl}_{\text{rad}}\text{H}$ to the electron-rich anionic $\text{Fl}_{\text{red}}\text{H}^-$ species creates an electrostatically unfavorable interaction with the electron-rich phenolic tyrosine sidechain.

In model studies, the modulation of flavin redox potentials by aromatic stacking interactions has been studied through the use of bidentate hydrogen bonding-aromatic stacking receptors. (Figure 7). Using this host-guest complex, the favorable interactions between the electron-rich aromatic moiety on the receptor and the electron-deficient oxidized flavin were demonstrated through the increasing association constant (K_a) with increasing aromatic-aromatic overlap. Using the non-stacking phenyl receptor as a control, we can see that aromatic stacking in the anthracyl receptor-flavin complex is worth 2 kcal mol⁻¹ in free energy (ΔG). As with their biological prototype, aromatic-aromatic overlap makes the flavin reduction potential more negative. This change in potential arises from the loss of aromatic-

Figure 7. Molecular modeling structure (AMBER) of the flavin **1**–receptor **6** complex and thermodynamic constants for host–guest binding in CDCl₃ at 298 K.

aromatic recognition that arises when flavin is converted from the electron-deficient Fl_{ox} state to the electron-rich Fl_{rad⁻} state; the lack of aromatic–aromatic recognition can be seen from the virtually identical K_a s for the various receptors with Fl_{rad⁻}.

The virtually identical binding constants observed with Fl_{rad⁻} for each of the receptors strongly suggests the possibility of conformational switching upon reduction of Fl_{ox} to Fl_{rad⁻} (Figure 8). This switching could serve a variety of roles in biological systems, such as controlling protein–protein interactions. This kind of conformational adjustment also provides a potential tool for the creation of molecular devices.

To explore further the possibility of redox-controlled conformational switching in π -stacked systems, EPR experiments were performed on the above systems with analogous naphthalimide radical anion (N_{rad⁻}) systems (Figure 9). These systems behaved similarly to the flavin-based host–guest systems; aromatic stacking of the naphthalimide in the oxidized state with the anthracenyl receptor was manifested by a more than 10-fold increase in binding relative to the phenyl-substituted control. Likewise, analogous to the flavin redox system, this relative enhancement disappeared upon reduction of the naphthalimide to the radical anion (N_{rad⁻}). In EPR experiments, there was no visible difference in the EPR spectrum of N_{rad⁻} (Figure 10) when bound to either the nonstacking phenyl receptor (Figure 9a) or the an-

Figure 8. Redox-based conformational switching of π -stacked systems.

Figure 10. EPR spectra of N_{rad}^- bound to (a) phenyl receptor and (b) anthracyl receptor.

thracyl receptor (Figure 9b). This indicates a total lack of interaction between the two aromatic systems in the anthracyl system, consistent with the hypothesis that a conformational switch process is operative. A corollary of this observation is that the modulation of redox potentials observed in these flexible systems is a lower bound for that possible in their enzymatic counterparts, where the redox cofactor is unable to flip away, and can be forced into proximity with the aromatic stacking unit by the protein scaffold.

2.2.3 Other Electrostatic Interactions

In addition to hydrogen bonding and aromatic stacking, it is clear that other electrostatic interactions will influence the reduction potential of redox-active systems. These interactions can be either long-range or local in nature. One example of long-range electrostatic interactions on cofactor reduction potentials is provided by the flavodoxins. In these systems, Zhou and Swenson have shown that the anionic phosphate functionality on the flavin mononucleotide (FMN) side-chain makes the potential for flavin reduction more negative [37]. This effect was mirrored in a mutagenesis study of anionic (glutamate and aspartate) residues within 13 Å of the flavin binding site of the *D. vulgaris* flavodoxin. In these studies, it was found that neutralization of these residues through mutation made the reduction of the flavin from the neutral $\text{Fl}_{\text{rad}}\text{H}$ state to the anionic Fl_{red}^- state, an average of 15 mV per residue more negative.

In complementary computational studies, Gunner et al. have explored the role of long-range electrostatic interaction on electron transfer processes in the *Rhodospira sphaeroides* reaction center [38]. The interaction domains were identified by mapping electrostatic potentials, calculated from the Poisson–Boltzmann equation, on to calculated ‘encounter surfaces’ for each of the components of the reaction center. From qualitative correlation of electron transfer processes with these low-resolution potential maps, it is apparent that long-range interactions profoundly affect the reduction potential of the cofactors in the reaction center.

There has been far less research performed on the role of short-range electrostatic interactions such as cation– π [39] and other polar– π [40] effects on the reduction potential of organic cofactors. The effects of these interactions on biological systems are hard to assess: mutation of charged residues near the active site perturbs multiple aspects of the catalytic process [41], whereas dipolar interactions are often subtle, and are extremely distance dependent [42]. One model study has been performed on the ‘donor atom– π ’ interaction of electron-rich functionality with flavins [43]. These studies used a model system (Figure 11) to explore the role of this interaction

Figure 11. Modulation of flavin recognition and redox processes through donor atom– π interactions.

Figure 12. PQQ and trimethyl ester/methylated pyrrole analog.

in recognition and redox processes. These studies demonstrate once again the selective interaction of electron-rich functionality with the electron deficient Fl_{ox} state of the flavin. One interesting observation in this system is that the strongest donor atom- π interaction, and hence reduction potential modulation, occurs with the thiomethyl substituent. It remains an open question as to whether this stronger interaction arises from polarization or geometrical effects; preliminary computational studies suggest the latter [44].

Another aspect of electrostatic modulation of redox systems is metal-cofactor interactions. Although these interactions are surprisingly uncommon in biological systems, metal-cofactor interactions have been well documented in certain families of enzymes such as bacterial alcohol dehydrogenases. These enzymes utilize the pyrroloquinolinequinone (PQQ) system as a redox cofactor (Figure 12) [45]. In these systems, it has been established that Ca^{2+} serves as additional cofactors in the enzymatic processes catalyzed by PQQ-dependent proteins [46].

In recent model studies [47], Itoh et al. [48] used PQQ-Me₄ as an analog for PQQ to study the effects of Ca^{2+} interactions with PQQ. This peralkylated cofactor was chosen to simplify the electrochemistry of the naturally occurring cofactor which, as in the flavins, can serve as a proton source for electrochemical-chemical-electrochemical (ece) processes. Using this analog, it was established that Ca^{2+} binding had a profound impact on the reduction process, making the reduction of PQQ-Me₄ 570 mV (13 kcal mol⁻¹) less negative. The origin of this stabilization was explored using EPR studies coupled with semi-empirical calculations. Using this synergistic combination of methodologies, the structure of the PQQ-Me₄ radical anion was shown to chelate Ca^{2+} between the quinone carbonyl, the ester and the pyridine nitrogen as shown in Figure 13.

Figure 13. PQQ-Me₄ radical anion- Ca^{2+} complex.

2.3 Recognition-mediated Control of Molecular Orbital Geometries

In addition to modulating the reduction potentials of redox cofactors, noncovalent interactions affect the orbital geometries of these systems [49]. Changing the shape of the lowest unoccupied molecular orbital (LUMO) will alter the reduction of oxidized cofactors, while modification of the highest occupied molecular orbital (HOMO) will serve to modulate the oxidation of these cofactors when they are in their reduced states. The modification of redox properties arising from orbital distortion will be manifested thermodynamically through alteration of the reduction potentials of the cofactor. The distortion of orbital geometries should also alter the kinetics of electron transfer process by changing the vector of the transfer event, an effect that is not well explored. While clearly important to the understanding of redox processes, the structures of the HOMO and LUMO of molecular systems are not directly experimentally observable. This inability to correlate theory and experiment limits our ability to correlate orbital structure with molecular behavior and properties.

In contrast to the HOMO and LUMO, the singly occupied molecular orbital (SOMO) can be correlated both qualitatively and quantitatively with experimentally measurable EPR hyperfine couplings (hfcs). As a result, host-guest systems that have redox-active guests that are stable as radicals provide excellent tools for studying the effects of noncovalent interactions on redox properties.

One recent example of the redistribution of spin density by noncovalent interaction is the PQQ-Ca²⁺ system previously described (Figure 13). In this study, binding of the PQQ analog to Ca²⁺ increases the hfcs observed for the pyridine nitrogen, presumably indicating an increase in spin density at this position. Interestingly, the hfcs at the other positions of the cofactor analog were not substantially perturbed. The lack of longer range distortion of the SOMO is unusual, given the dramatic change in energetics observed upon complexation.

In recent studies, Rotello has quantitatively investigated the effect of hydrogen bonding on the spin density distribution of redox-active host radicals, using a combined EPR and density functional approach. In these studies, the radical anion of naphthalimide (N_{rad}^-) (Figure 14) was chosen as model for the flavin radical anion (Fl_{rad}^-) because of the high degree of symmetry of the naphthalene framework. This symmetry provides readily interpretable EPR spectra of high resolution, allowing direct determination of hfcs.

The spectra of N_{rad}^- and the N_{rad}^- -receptor complex that were acquired via simultaneous electrochemistry and EPR (SEEPR) are notably different. The spectrum of the hydrogen-bound radical, produced via addition of the diacyldiaminopyridine receptor, exhibits a greater overall signal width and concomitantly less overlap of hyperfine lines (Figure 15). Addition of the same receptor to *N*(1)-methylnaphthalimide radical anion, where the binding site is blocked through alkylation, had only negligible effects on the SEEPR spectrum of the control. This confirms that specific hydrogen bond interactions were the cause of the changes observed in the spectrum of N_{rad}^- .

Figure 14. Hydrogen-bonded complex between naphthalimide radical anion (N_{rad}^-) and diacyl-diaminopyridine receptor, and the negative control *N*(1)-methyl-naphthalimide, in which the binding site is blocked via alkylation.

Figure 15. Low-field half of the SEEPR spectra of (a) N_{rad}^- and (b) the N_{rad}^- -receptor complex.

Despite the complexity of the observed spectrum of N_{rad}^- , spectral simulation and iterative curve fitting permitted the precise determination of hfcs for hydrogen-bound and free N_{rad}^- . Hydrogen bonding to the hydrogen-bonding receptor enhances the spin polarization of N_{rad}^- , which is manifested in the increased spectral width. Additionally, in contrast to the PQQ analog, changes are seen in all the observed hyperfine couplings, indicating an overall redistribution of spin density.

In addition to qualitative correlation to spin density distribution, the experimental hfcs provided critical benchmarks for the validation of *ab initio* computational studies of radical systems, through the relationship

$$a(\text{N}) = (8\pi/3)g_e\beta_e g_N\beta_N\rho(r_N) \quad (2)$$

where the hfc of nucleus N, $a(\text{N})$, is proportional to the corresponding Fermi contact integral (spin density at the nucleus) $\rho(r_{\text{N}})$; g_e (g_{N}) represents the electronic (nuclear) g -factor and β_e (β_{N}) the Bohr (nuclear) magneton.

In the EPR studies of the N_{rad^-} host-guest complexes, DFT-B3LYP-predicted hfcs for N_{rad^-} and the N_{rad^-} -receptor system were in good overall quantitative agreement with experimental results (Table 1). This validates the wavefunction for N_{rad^-} and the hydrogen-bound complex, allowing us to predict properties not experimentally accessible, such as electrostatic potential (see above), electron density and spin density distribution (Figure 16).

According to the DFT-B3LYP calculations, complexation by the receptor shifts the spin density away from the carbonyl oxygens involved in hydrogen bonding, and towards the carbonyl carbons C(2) and C(9) (Figure 16). The largest increase in spin density, however, is observed in the naphthyl core of C(3)-C(8). This migration of spin density can be understood through examination of the molecular orbitals of N_{rad^-} . Since hydrogen bonding is a two-electron process, it will cause a distortion of lower, filled molecular orbitals towards the hydrogen-bonding recognition surface, leading to an increase in charge density at the carbonyl oxygens. To maintain orthogonality between wavefunctions, the SOMO will then be distorted away from the binding site, and into the naphthalene ring system. This

Figure 16. Change in the absolute spin density of N_{rad^-} upon complexation with diacyldiaminopyridine receptor, as predicted by DFT-B3LYP calculations. Numbers in parantheses: $1000 \times (|\text{sd}(N_{\text{rad}^-} + \text{receptor})| - |\text{sd}(N_{\text{rad}^-})|)$.

Figure 17. (a) Duroquinone radical anion. (b) Asymmetric duroquinone radical anion–imidazole complex.

result provides a possible solution to an apparent paradox in flavoenzyme electron transfer. In solution, spin density for Fl_{rad}^- is centered at N(5), whereas electron transfer processes occur through C(8) of the xylene ring. If an effect similar to that observed in the N_{rad}^- –receptor complex occurs in the flavin radical anion–protein complex, a movement of spin density away from the hydrogen bonding surface and towards the distal xylene ring will occur, facilitating the electron transfer event.

Computational methodologies also provide a powerful tool for the study of biological systems. In recent studies, O'Malley used DFT-B3LYP methods to explore the hydrogen bonding environment within the Q_a site of the *Rhodobacter sphaeroides* photosynthetic reaction center [50]. In these studies, the effects of symmetric and asymmetric hydrogen bonding on the hyperfine couplings of the duroquinone radical anion (Figure 17) were predicted using the B3LYP hybrid functional. In these studies, it was found that there was excellent agreement between the hfcs calculated for the duroquinone–imidazole complex and experimentally measured hfcs from a duroquinone-constituted photosynthetic reaction center [51].

2.4 Proton-coupled Electron Transfer

Proton-coupled electron transfer is a prominent theme in biological redox systems. There are three basic mechanisms for these processes (Figure 18). In the first mechanism (path A), electron transfer occurs prior to proton transfer. This mechanism is commonly observed for the electrochemical reduction and oxidation of quinones and flavins in protic media [52]. In this interfacial environment, proton transfer is manifested as an ECE (E represents an electron transfer at the electrode surface and C represents a homogeneous chemical reaction) two-electron reduction of these systems to their fully reduced states (Figure 19). As electron transfer occurs prior to the proton transfer event, proton transfer does not affect either the redox potential or the electron transfer rate to or from the cofactor.

In contrast to post-reduction proton transfer, transfer of the proton to the redox species prior to electron transfer (Figure 18, path B) has a profound impact on re-

Figure 18. Proton-dependent electron transfer pathways.

Figure 19. Schematic representation of the ECE pathway for two-electron reduction of flavins in aprotic media.

duction potentials and electron transfer rates. At the simplest level, protonation followed by electron transfer can be observed in acidic solutions, where the process has been termed ‘catalysis of electron transfer’ by Fukuzumi (see chapter 1 in this volume) [53]. In these systems the redox-active unit is protonated by the acidic solution, rendering the reduction potential of the redox system substantially less negative, directly analogous to the effects of hydrogen bonding previously mentioned. This lowering in reduction potential results in what is essentially specific acid catalysis of the electron transfer process.

While studies of specific acid catalysis of redox cofactors shed light on the intricacies of the electron transfer process [54], the conditions required for pre-protonation of the cofactor are highly acidic ($\text{pH} < 0$), and would not generally be found in biological systems. There are, however, systems such as Q_B reduction in the *Rhodobacter sphaeroides* reaction center [55], where kinetic data indicate proton transfer prior to or simultaneous with electron transfer. This would seem to indicate that a ‘general acid’ process is operative. At first glance, this sort of mechanism would seem to be contrary to the Born–Oppenheimer approximation. This apparent paradox can be avoided, however, if quantum chemical (nonadiabatic) processes are considered.

In recent research, the concept of simultaneous electron and proton transfer has been explored. In this process, directly coupled electron and proton transfer result in the formal transfer of a hydrogen atom (Figure 18, path C). In this pathway, two quantum events occur: electron tunneling and proton tunneling [56]. Whereas electron tunneling is a well-accepted phenomenon, proton tunneling is a far less commonly invoked property. Proton tunneling can be readily understood if we consider

the de Broglie wavelength of the proton, which is 0.5 \AA when the particle has an energy of $\sim 2 \text{ kcal mol}^{-1}$. Given that the distance required to transfer a proton from a hydrogen bond donor to an acceptor is on the order of 0.7 \AA , proton tunneling coupled to protein–cofactor motion is clearly a possibility.

Evidence for the dual proton and electron tunneling process required for simultaneous electron and proton transfer has been obtained from both enzymatic and model systems. In biomolecular systems, the strongest evidence for proton tunneling processes is obtained from kinetic isotope effects, where both anomalously high protium–tritium kinetic isotope effects and distinct temperature profiles for these isotope effects can be used as diagnostic tools for proton tunneling events [57].

For proton tunneling to occur efficiently, the donor and acceptor must be in the intimate proximity provided by hydrogen bonding. This contact is a natural feature in biological systems, and has been replicated in model systems through the use of hydrogen-bonded donor–acceptor pairs [58]. In one series of experiments, Therien et al. compared photoinduced charge transfer between covalently linked systems and the analogous transfer in hydrogen-bonded donor–acceptor pairs (Figure 20) [59]. In these studies, it was determined that the electron transfer rate in the hydrogen-bonded system (Figure 20a) was twice that of the covalently linked analog (Figure 20b), despite the fact that the thermodynamic driving force in the covalently linked system was more favorable (-0.87 versus -0.70 eV for the hydrogen-bonded system).

Further insight into the nature of proton-coupled electron transfer can be obtained from donor–acceptor pairs featuring an asymmetric hydrogen bonding in-

Figure 20. (a) Noncovalently and (b) covalently linked donor–acceptor pairs.

Figure 21. Hydrogen-bonded donor–acceptor pairs featuring (a) amidinium–carboxylate, (b) carboxylate–amidinium and (c) biscarboxylate interfaces.

terface. In recent studies, Nocera et al. used ruthenium tetramethylbipyridyl (tmby) systems to explore electron transfer processes (Figure 21) [60]. In these models, photoinduced electron transfer from the Ru^{2+} to the complementary dinitrobenzene acceptors provides an elegant system for the study of electron transfer in hydrogen-bonded systems. Using amidinium–carboxylate and carboxylic acid–carboxylic acid dimerization to provide the proton-transfer conduit, it was found that proton-coupled electron transfer in the carboxylate–amidinium system (Figure 21b) was 37-fold faster than the analogous amidinium–carboxylate donor–acceptor pair (Figure 21a), and seven-fold faster than the biscarboxylate system (Figure 21c). The difference in rates is attributed to the neutralization of the charged interface of the carboxylate–amidinium system upon electron or proton transfer. This highly favorable process is expected to play a key role in hydrophobic environments, and is probably a central factor in controlling electron transfer in biological systems [61].

2.5 Summary and Outlook

Recognition processes are clearly central to the control of cofactor redox properties in biological systems. This control is manifested in multiple aspects of the redox process, including redox potentials, orbital geometries, protonation states and electron transfer pathways. In all of these areas, study of model systems and their biological prototypes has provided considerable insight into the interplay of enzyme–cofactor noncovalent interactions and cofactor redox processes. While much remains to be explored with both biomolecular and model studies, perhaps the greatest challenge will be the integration of these two approaches, using the tools provided by computational chemistry. This integration will ultimately provide a comprehensive understanding of complex biomolecular processes at the electronic, molecular and supramolecular level. This understanding is important both biologically and synthetically, where redox-based molecular devices provide new solutions to pragmatic problems.

3 Homogeneous Redox Catalysis in CO₂ Fixation

Etsuko Fujita and Bruce S. Brunschwig

3.1 Introduction

The twin problems of global warming and diminishing finite fossil fuels resources have stimulated research into CO₂ fixation and utilization [1, 2]. Natural photosynthetic CO₂ fixation utilizes sunlight and chlorophyll as the energy source and photocatalyst to generate carbohydrates and oxygen from CO₂ and H₂O. Natural photosynthesis occurring over a few hundred million years has created a vast quantity of fossil fuels that at present fill our energy needs. Unfortunately, current consumption rates are rapidly depleting our supply of fossil fuels. Even with the advent of fuel farms it is unlikely that natural photosynthesis will be able to balance the production and use of fuels. It is therefore necessary to explore alternative routes to fuel (and chemical) production and it is likely that artificial photosynthesis will play an increasingly important role in the future.

Because of the thermodynamic stability and chemical inertness of CO₂, both energy and catalysts are needed to transform CO₂ into fuels or useful chemicals [3–5]. The large energy input needed to fix CO₂ requires the use of renewable energy if artificial CO₂ fixation is carried out on a large scale. The reduction potential to convert CO₂ to CO₂^{•-} is –1.9 V vs. NHE, making this process highly unfavorable. In fact, 0.1 – 0.6 V overpotentials are typically for the single-electron reduction of CO₂ at Pt or Hg working electrodes. This overvoltage partially results from the kinetic barrier arising from the geometric changes required for one-electron reduction of CO₂ (CO₂ is linear whereas CO₂^{•-} is bent). Although CO₂ reduction by the proton-assisted multielectron steps shown in Table 1 is often kinetically difficult, these steps are more favorable thermodynamically than the one-electron process.

Since the two-electron reduction to formic acid or CO requires a lower potential, electrolysis using a multielectron transfer catalyst in aqueous or in low-protic media can be carried out at considerably lower voltages. The simplest electrocatalytic system for CO₂ reduction is an electrochemical cell that contains: a working electrode, a reference electrode, a homogeneous electrocatalyst, the supporting electro-

Table 1. Reduction potentials for CO₂ at pH 7 with all other solutes at 1 M.

Reaction	$E_{1/2}'$ (V) ^a	
$\text{CO}_2 + \text{e}^- \rightarrow \text{CO}_2^{\cdot -}$	-1.9	(1)
$\text{CO}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{HCO}_2\text{H}$	-0.61	(2)
$\text{CO}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{CO} + \text{H}_2\text{O}$	-0.53	(3)
$\text{CO}_2 + 4\text{H}^+ + 4\text{e}^- \rightarrow \text{C} + 2\text{H}_2\text{O}$	-0.20	(4)
$\text{CO}_2 + 4\text{H}^+ + 4\text{e}^- \rightarrow \text{HCHO} + \text{H}_2\text{O}$	-0.48	(5)
$\text{CO}_2 + 6\text{H}^+ + 6\text{e}^- \rightarrow \text{CH}_3\text{OH} + \text{H}_2\text{O}$	-0.38	(6)
$\text{CO}_2 + 8\text{H}^+ + 8\text{e}^- \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$	-0.24	(7)
$\text{CO}_2 + 2\text{e}^- \rightarrow \text{CO}_2^{2-}$	-1.55	(8)
$\text{CO}_2^- + \text{e}^- \rightarrow \text{CO}_2^{2-}$	-1.2	(9)

^a Values are for aqueous solution vs. NHE. The $E_{1/2}'$ values are close to the values in acetonitrile vs. SCE because the ferricenium/ferrocene redox potential shifts by 0.25 V (vs. SCE) on going from acetonitrile to water while the SCE potential in water is 0.24 V [6, 7].

lyte, CO₂ and an oxidizable species (often the solvent or CO₂). The electrodes, such as those made of Mg, can be used as the oxidizable species. A heterogeneous catalyst attached to the electrode surface can be used in place of the homogeneous electrocatalyst.

The prototypical photochemical system for CO₂ reduction contains a photosensitizer (or photocatalyst) to capture the photon energy, an electron relay catalyst (that might be the same species as the photosensitizer) to couple the photon energy to the chemical reduction, an oxidizable species to complete the redox cycle and CO₂ as the substrate. Figure 1 shows a cartoon of the photochemical CO₂ reduction system. An effective photocatalyst must absorb a significant part of the solar spectrum, have a long-lived excited state and promote the activation of small molecules. Both organic dyes and transition metal complexes have been used as photocatalysts for CO₂ reduction. In this chapter, CO₂ reduction systems mediated by cobalt and nickel macrocycles and rhenium complexes will be discussed.

3.2 Macrocyclic Complexes of Cobalt and Nickel

3.2.1 Overview of CO₂ Reduction Systems Mediated by Cobalt and Nickel Macrocycles

Many 14-membered tetraazamacrocyclic complexes of cobalt and nickel serve as catalysts for electrochemical CO₂ reduction to produce CO and H₂ in water, acetonitrile–water or organic solvents [8–11]. The structures of the macrocycles are shown in Figure 2. Among these, Ni(cyclam)²⁺ is a very effective and selective catalyst for the electrochemical reduction of CO₂ to CO [10, 11]. Ni(cyclam)⁺ ad-

Figure 1. Artificial photo-synthetic scheme.

sorbed on the surface of the mercury electrode has been shown to be the active species. $\text{Ni}(\text{cyclam})^{2+}$ can have at least two isomers in solution (Figure 2) and studies on configurationally pure nickel complexes similar to $\text{Ni}(\text{cyclam})^+$ have been carried out to measure the activity of different isomers [12]. Structural differences are an important factor for both CO_2 binding and catalyst adsorption on mercury.

CoHMD^{2+} homogeneously catalyzes both electroreduction of CO_2 and water reduction in water, water–acetonitrile or DMF solutions [8, 9]. The CO -to- H_2 ratio produced is typically less than 1 and strongly depends on the experimental conditions used (i.e., applied potential, amount of water, electrolysis time, etc). The chiral N–H centers of the HMD macrocycle give rise to two isomers, *N-rac* and *N-meso*, as shown in Figure 2. The *N-rac* isomers of both $\text{Co}^{\text{II}}\text{HMD}^{2+}$ and $\text{Co}^{\text{I}}\text{HMD}^+$ predominate in MeCN (>90 %) and water at room temperature. The equilibrium between the *N-rac* and *N-meso* cobalt(II) isomers is very slowly established in acidic aqueous and organic media ($<2 \times 10^{-7} \text{ s}^{-1}$); by contrast, equilibration of the cobalt(I) isomers is relatively rapid ($>2 \times 10^3 \text{ s}^{-1}$) [13, 14].

Photochemical CO_2 reduction to CO (and formate in some cases) has been reported in a catalytic system using $\text{Ru}(\text{bpy})_3^{2+}$ as the sensitizer, nickel or cobalt macrocycles as the electron relay catalyst, and ascorbate as a sacrificial reductive quencher [9, 15, 16]. These systems also produce H_2 via water reduction. Although $\text{Ni}(\text{cyclam})^{2+}$ is an efficient and selective catalyst for electrochemical CO_2 reduc-

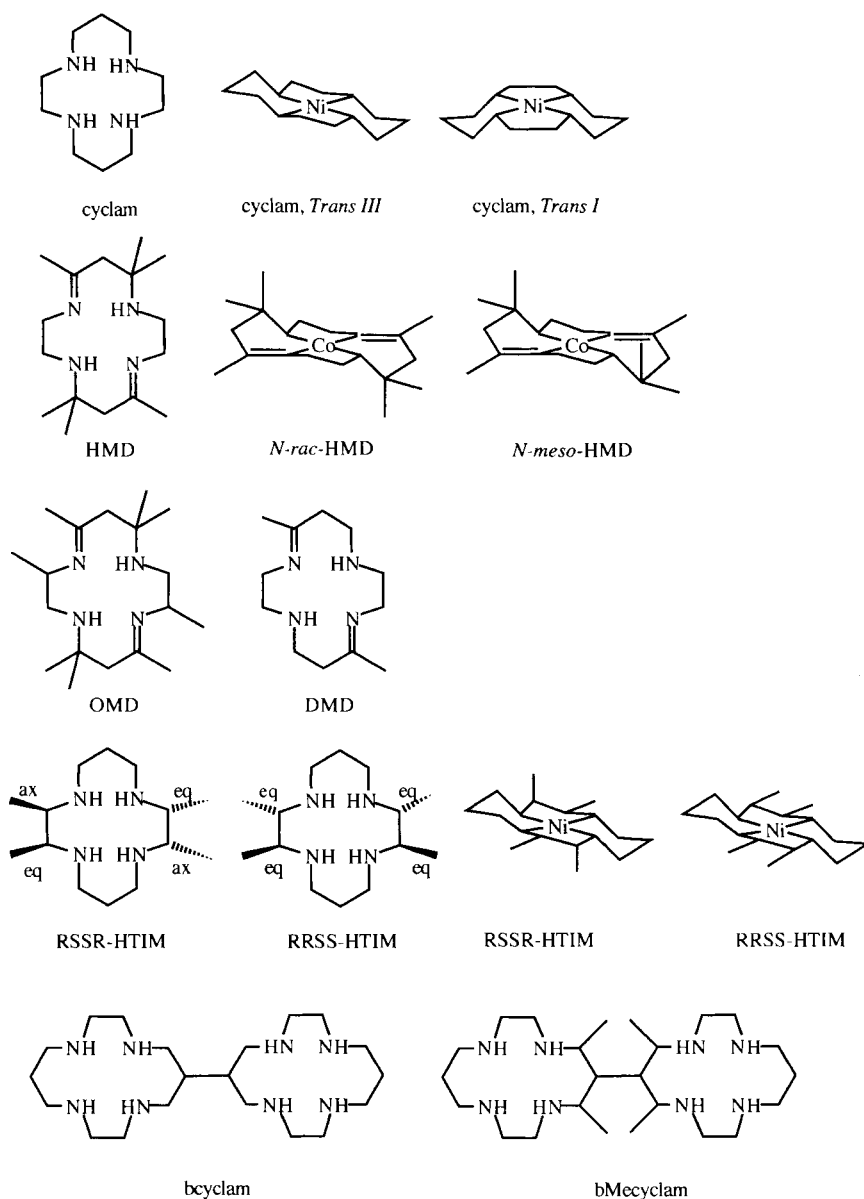

Figure 2. Structures and geometries of metal macrocycles.

tion, even in H_2O , when used as a homogeneous catalyst for photochemical reduction, the quantum yield and selectivity for CO formation are low. The yields of CO and H_2 are pH dependent and typically more H_2 than CO is produced.

Photoreduction of CO_2 with *p*-terphenyl as the photosensitizer and a tertiary

amine as a sacrificial electron donor has been demonstrated [49]. The addition of a cobalt macrocycle enhances the activity of the TP by suppressing degradative reactions of the TP and produces CO and formate efficiently with only small amounts of H₂ [17].

Metal(I), metal(III) hydride and metallocarboxylate complexes have all been postulated as intermediates in electro- and/or photochemical CO₂ reduction. These intermediates are discussed in the next sections.

3.2.2 Properties of the Cobalt and Nickel Macrocycles

M(I) complexes

Reduction potentials of Ni^{II}(cyclam)²⁺, *RRSS*-Ni^{II}HTIM²⁺ and Co^{II}HMD²⁺ are −1.44, −1.43 and −1.34 V (vs. SCE in MeCN), respectively [18]. The metal(I) complexes can be prepared by electrochemical or Na–Hg reduction, or pulse radiolysis. The spectra of all the M(I) species show a strong MLCT (metal-to-ligand charge transfer) band in the visible region (λ_{max} , ϵ): Ni^I(cyclam)⁺ at 384 nm, 4400 M^{−1} cm^{−1}; *RRSS*-Ni^IHTIM⁺ at 388 nm, 4340 M^{−1} cm^{−1} and Co^IHMD⁺ at 678 nm, 18000 M^{−1} cm^{−1} in MeCN [18]. In the square-planar d⁸-Co^IHMD⁺, the electron-rich cobalt(I) center donates significant electron density to the imine moiety, causing the C=N stretching frequency (1571 cm^{−1}) to be much lower than for Co^{II}HMD²⁺ (1661 cm^{−1}) [19]. Interestingly, the square-planar d⁹-NiHMD⁺ complex donates less electron density: the C=N stretching frequency only shifts from 1655 to 1647 cm^{−1} upon the reduction ($E_{1/2}$ = −1.22 V vs. SCE in MeCN) [20]. EXAFS and X-ray structures reveal that the Co–N bond distances remain almost the same upon the reduction of the Co(II) macrocycles in both solid and solution [20, 21].

Square-planar d⁸-Ni(cyclam)(ClO₄)₂ and *RRSS*-NiHTIM(ClO₄)₂ can be crystallized from water as low-spin complexes. However, in solution the Ni(II) complexes can exist as high-spin, octahedral complexes and/or as low-spin, square-planar complexes depending on solvent [18]. For example, Ni^{II}(cyclam)²⁺ and Ni^{II}HTIM²⁺ are low spin in MeNO₂, high spin in MeCN and the high- and low-spin complexes are in equilibrium in water. EXAFS studies reveal that *RRSS*-Ni^{II}HTIM²⁺ and *RRSS*-Ni^IHTIM⁺ are six- and four-coordinate with average Ni–N distances of 2.08 and 2.05 Å, respectively, in MeCN [22]. The X-ray structures of square-planar *RSSR*-Ni^{II}HTIM(ClO₄)₂ (average Ni–N distance 1.959 Å) and *RSSR*-Ni^IHTIM(ClO₄) (average Ni–N distance 2.068 Å) indicate that the bond lengths in the Ni(I) macrocycles increase by 0.11 Å on reduction [18]. This suggests that the Ni^{I/II} self-exchange rates of both Ni(cyclam) and NiHTIM complexes in H₂O or MeCN should be slow owing to the large structural changes upon electron transfer. The rate constant for the self-exchange reaction between Ni(cyclam)* and Ni(cyclam)²⁺ has been calculated to be 1 × 10^{−3} M^{−1} s^{−1} using the Marcus cross relation [25].

Some electron-transfer rates are summarized in Table 2. Owing to the large driving force for most of the reactions (>1.1 V except that involving Ru(bpy)₃⁺), the

Table 2. Comparison of electron transfer rates at 25 °C^a.

Reaction	Complex	k (M ⁻¹ s ⁻¹)	Ref.
$\text{ML}^{2+} + \text{e}^-_{\text{aq}} \rightarrow \text{ML}^+$	Ni(cyclam) ²⁺	5.6×10^{10}	23
	Ni(cyclam) ²⁺	4.1×10^{10}	24
	Ni(cyclam) ²⁺	3.8×10^{10}	25
	<i>N-rac</i> -CoHMD ²⁺	4.4×10^{10}	26
	<i>N-meso</i> -CoHMD ²⁺	4.7×10^{10}	14
$\text{ML}^{2+} + \text{TP}^{\bullet-} \rightarrow \text{ML}^+ + \text{TP}$	Ni(cyclam) ²⁺	4.3×10^9	27
	<i>N-rac</i> -CoHMD ²⁺	1.1×10^{10}	28
	CoOMD ²⁺	1.1×10^{10}	28
	CoDMD ²⁺	8.8×10^9	28
$\text{ML}^{2+} + \text{Ru}(\text{bpy})_3^+ \rightarrow \text{ML}^+ + \text{Ru}(\text{bpy})_3^{2+}$	<i>N-rac</i> -CoHMD ²⁺	1.8×10^8	29

^a The reaction rates with e^-_{aq} are measured in water. The electron-transfer rate from $\text{TP}^{\bullet-}$, which has a potential estimated at about -2.5 V, is measured in MeCN. The electron-transfer rate from $\text{Ru}(\text{bpy})_3^+$, which has a potential of -1.33 V, is measured in H₂O.

rates constants are mostly $>10^{10} \text{ M}^{-1} \text{ s}^{-1}$ and are at or near the diffusion-controlled limit.

M–H complexes

Although both cobalt(I) and nickel(I) macrocycles are stable in dry, degassed MeCN, their lifetimes in water are limited because the M(I) complexes can react with protons to form the corresponding metal hydrides, M(III)–H, as shown in Eq. 10 [14, 18]:

The thermodynamics and kinetics of H⁺ binding to cobalt(I) and nickel(I) macrocycles have been determined. The $\text{p}K_{\text{a}}$ of Ni(cyclam)(H)²⁺, *RRSS*-NiHTIM(H)²⁺ and *N-rac*-CoHMD(H)²⁺ are 1.8, 1.9 and 11.7, respectively [14, 24, 27]. As seen from Table 3, protonation rate constants for *N-rac*-CoHMD⁺ depend on acid strength. The results are consistent with an associative reaction of the square-planar complex with an acid, HA. Whereas the spectrum of *N-rac*-CoHMD(H)²⁺ suggests the formation of a $[\text{Co}^{\text{III}}(\text{H}^-)]^{2+}$ species with an absorption band at 440 nm ($520 \text{ M}^{-1} \text{ cm}^{-1}$), Ni(cyclam)(H)²⁺ shows no significant absorbance in the 300–700 nm region [14, 24].

M–CO₂ complexes

The reversible binding of CO₂ to M^IL⁺ has been studied using differential pulse polarography [30], cyclic voltammetry [19, 31], pulse radiolysis [14, 24], flash photolysis [24, 28] and conventional spectroscopic methods [19, 32]. The results

Table 3. Rate constants for protonation of M(I)L⁺ by acid (HA).

are summarized in Table 4. The CO₂ binding constants of *N-meso*- and *N-rac*-Co^IHMD⁺ are different in both H₂O and MeCN.

The CO₂ binding constant for the *N-rac* isomer is about 100 times greater than that for the *N-meso* isomer in both solvents. The difference is primarily due to steric interactions between the bound CO₂ and the macrocycle. While hydrogen bonding between the bound CO₂ and amine protons of the macrocycle stabilizes both adducts, the *N-meso* adduct is destabilized by steric repulsion between the macrocycle methyl groups and the CO₂ molecule. The equilibrium constants for the formation of CoHMD(CO₂)⁺ and Ni(cyclam)(CO₂)⁺ are ~10⁴ and 4 times larger in water than in MeCN, respectively. Water may stabilize the CoHMD(CO₂) complex by forming hydrogen bonds to the bound CO₂ as found in crystals of [Ru(bpy)₂(CO)(COO)] · 3H₂O [33]. However, both CoHMD(CO₂)⁺ and Ni(cyclam)(CO₂)⁺ have shorter lifetimes in water than in MeCN owing to subsequent reactions.

A redox potential threshold for CO₂ binding to the cobalt macrocycles seems to occur at ~-1.2 V vs. SCE [19]. The CO₂ binding constants for a series of Co(I) macrocycles show a strong correlation with the Co^{II/I} potential. This trend is consistent with charge transfer from the electron-rich cobalt center to the bound CO₂. The CO₂ binding rate constants in MeCN–MeOH seem also to correlate with the Co^{II/I} potential in MeCN: 1.1 × 10⁶ M⁻¹ s⁻¹ for Co^IOMD⁺, 1.7 × 10⁸ M⁻¹ s⁻¹ for Co^IHMD⁺ and 3.7 × 10⁸ M⁻¹ s⁻¹ for Co^IDMD⁺.

^a Numbers in parentheses are calculated values.^b Measured vs. SCE.^c Measured vs. ferricenium/ferrocene.^d K_{CO_2} is assumed to be the same as K_{I_2} in Eq. 12.

Although the *N-rac*- $\text{CoHMD}(\text{CO}_2)^+$ adduct decomposes to *N-rac*- CoHMD^{2+} and CO in wet MeCN, it is stable in dry MeCN under a CO_2 atmosphere. The complex is thermochromic, being purple at room temperature and yellow at low temperature [34]. The 530 nm band diminishes in intensity and a 430 nm band increases in intensity as the temperature drops. Measurements over the range -40 to $+40^\circ\text{C}$ give $K_{13}(298) = 0.11 \pm 0.13$, $\Delta G^\circ(298) \approx 1.3 \text{ kcal mol}^{-1}$, $\Delta H^\circ = -7.0 \text{ kcal mol}^{-1}$ and $\Delta S^\circ = -28 \text{ cal K}^{-1} \text{ mol}^{-1}$ for Eq. (13) in MeCN.

A solid sample, obtained at -70°C from a THF–MeCN mixture, shows $\nu_{\text{C=O}} = 1558 \text{ cm}^{-1}$, $\nu_{\text{C=N}} = 1653 \text{ cm}^{-1}$ and two $\nu_{\text{C=N}}$, 2337 cm^{-1} (for coordinated MeCN) and 2272 cm^{-1} (for free MeCN), consistent with the formation of $[\text{S-CoHMD}(\text{CO}_2)]^+$ with $\text{S} = \text{MeCN}$. Increasing pressure also causes the color to change. An MeCN solution contains $\sim 80\%$ five-coordinate $[\text{CoHMD}(\text{CO}_2)]^+$ and $\sim 20\%$ six-coordinate $[\text{CoHMD}(\text{CO}_2)(\text{MeCN})]^+$ under atmospheric pressure at 15°C . Increasing pressure shifts the equilibrium toward the six-coordinate species

Figure 3. Structures of the CoHMD(CO₂)⁺ species observed by FTIR.

with an overall reaction volume $\Delta V^\circ = -17.7 \text{ mL mol}^{-1}$ [35]. Furthermore, the FTIR spectra measured over the range 25 to -75°C in a CD₃CN–THF mixture indicate the existence of four CO₂ adducts: a five-coordinate, non-hydrogen-bonded form **A** ($\nu_{\text{C=O}} = 1710 \text{ cm}^{-1}$, $\nu_{\text{NH}} = 3208 \text{ cm}^{-1}$), a five-coordinate intramolecular hydrogen-bonded form **B** ($\nu_{\text{C=O}} = 1626 \text{ cm}^{-1}$), a six-coordinate non-hydrogen-bonded form **C** ($\nu_{\text{C=O}} = 1609 \text{ cm}^{-1}$, $\nu_{\text{NH}} = 3224 \text{ cm}^{-1}$) and a six-coordinate intramolecular hydrogen-bonded form **D** ($\nu_{\text{C=O}} = 1544 \text{ cm}^{-1}$, $\nu_{\text{NH}} = 3145 \text{ cm}^{-1}$) (see Figure 3). The two five-coordinate (**A** and **B**) and two six-coordinate (**C** and **D**) species have similar UV–vis spectra, so only two species are observed by UV–vis spectroscopy.

The thermochromic behavior of the CO₂ adducts has been studied by X-ray absorption spectroscopy [20]. The metal coordination number, geometry and electronic properties can be studied using X-ray absorption near-edge spectroscopy (XANES) and metal–ligand bond distances can be obtained through analysis of the extended X-ray absorption fine structure (EXAFS). XANES spectra for a series of the CoHMD complexes are shown in Figure 4. The X-ray absorption edge position of the CoHMD complex is sensitive to the oxidation state of the cobalt. The edge energy of Co^{II}HMD²⁺ decreases (1 eV) upon reduction and increases (2 eV) upon oxidation, as can be seen in Figure 4a. The $1s \rightarrow 4p_z$ pre-edge peak, located $\sim 6 \text{ eV}$ below the main edge, in the XANES spectrum for Co^{II}HMD²⁺ is characteristic of a four-coordinate square-planar geometry. The XANES spectrum of the CO₂ adducts at room temperature and 150 K are shown in Figure 4b. At room temperature the Co–CO₂ adduct is 90 % five-coordinate CoHMD(CO₂)⁺ and 10 % six-coordinate S–CoHMD(CO₂)⁺, whereas cooling the solution to 150 K results in 100 % conversion to the six-coordinate species [19]. The edge position of CoHMD(CO₂)⁺ at room temperature is similar to that of Co^{II}HMD²⁺, consistent with theoretical predictions [36, 37] that the bound CO₂ receives significant electron density (~ 0.7 of an electron) mainly from the Co d_{z^2} orbital. The XANES spectrum for S–CoHMD(CO₂)⁺ at 150 K shows an increase of the $1s \rightarrow 3d$ peak ($\sim 11 \text{ eV}$ below the main edge) and almost complete loss of the $1s \rightarrow 4p_z$ transitions, indicative of six-coordinate distorted octahedral geometry. The six-coordinate S–CoHMD(CO₂)⁺ species shows a 1.2 eV shift towards Co(III) and is interpreted

Figure 4. XANES for CoHMD complexes. (a) $[\text{Co}^{\text{II}}\text{HMD}](\text{ClO}_4)_2$ in acetonitrile at 150 K (—), $[\text{Co}^{\text{III}}\text{HMD}(\text{CO}_3^{2-})]\text{ClO}_4$ in H_2O at room temperature (\cdots) and $[\text{Co}^{\text{I}}\text{HMD}(\text{CO})]\text{ClO}_4$ in acetonitrile at room temperature (---). (b) $[\text{Co}^{\text{II}}\text{HMD}](\text{ClO}_4)_2$ in acetonitrile at 150 K (—), five-coordinate $[\text{CoHMD}(\text{CO}_2)]\text{ClO}_4$ in acetonitrile at room temperature (---) and six-coordinate $[\text{S-CoHMD}(\text{CO}_2)]\text{ClO}_4$ in acetonitrile at 150 K ($\cdots\cdots$).

as a $\text{Co}^{\text{III}}\text{-CO}_2^{2-}$ carboxylate complex. This assignment is consistent with the change of the CO_2 asymmetric stretch, $\nu_{\text{C=O}}$, from 1710 cm^{-1} for $\text{CoHMD}(\text{CO}_2)^+$ to 1544 cm^{-1} for $\text{S-CoHMD}(\text{CO}_2^{2-})^+$ discussed above. Although the cobalt(III) carboxylates have been postulated as intermediates in CO_2 reduction and water-gas shift reactions, the XANES results provide the first unambiguous evidence that active metal catalysts, such as $\text{Co}^{\text{I}}\text{HMD}^+$, can promote two-electron transfer to the bound CO_2 . The conversion of the $\text{M}^{\text{I}}\text{CO}_2$ species to a metallo-carboxylate, $\text{M}^{\text{III}}(\text{CO}_2^{2-})$, is an important step in catalytic CO_2 reduction since it avoids the very high-energy CO_2^- species.

3.2.3 Electrocatalytic Systems

$\text{Ni}(\text{cyclam})^{2+}$ is a very effective and selective catalyst for the electrochemical reduction of CO_2 [10, 11]. The advantages of the catalyst are high turnover frequencies (up to $10^3\text{ cycles h}^{-1}$), accessibility of the applied potential, high efficiency, good selectivity of CO formation at pH 4 and stability of the catalyst after a large number of turnovers ($>10^4$). $\text{Ni}(\text{cyclam})^+$ adsorbs on the surface of the mercury electrode and the adsorbed complex is the active catalyst. $\text{Ni}(\text{cyclam})^{2+}$ has configurational isomers in solution; the most stable two forms (*trans III*, 85 % and *trans I*, 14 % in water) are shown in Figure 2. It is possible to lock the cyclam ligand in one configuration (*trans III*) by adding methyl groups to the six-membered ring as in HTIM. The catalytic activities of pure stereoisomers, *RRSS*- and *RSSR*- NiHTIM^{2+} , have been studied [12]. These isomers do not show any isomerization in solution. *RRSS*- NiHTIM^{2+} , which has no axial methyl groups, shows much higher catalytic activity than *RSSR*- NiHTIM^{2+} . *RRSS*- NiHTIM^{2+} has larger cat-

alytic currents and more positive potentials for CO₂ reduction than Ni(cyclam)²⁺. The peak current density of the *RSSR*-NiHTIM²⁺, which has axial methyl groups, is lower than that of Ni(cyclam)²⁺ [12]. Thus structural differences may play an important role in adsorption of the metal complex on a mercury electrode and in CO₂ binding by the absorbed complex.

CoHMD²⁺ homogeneously catalyzes electroreduction of CO₂. However, it also catalyzes water reduction in water, water–acetonitrile and DMF solutions [8, 9]. The CO-to-H₂ ratio depends strongly on the experimental conditions used (i.e., applied potential, amount of water, electrolysis time, etc.) and is typically less than 1. Since the *pK_a* of CoHMD(H)²⁺ is 11.7, the hydride species also forms in CO₂-saturated water (pH ≈ 4) [8, 9] and is believed to be an intermediate in H₂ production.

3.2.4 Photocatalytic Systems

Systems with Ru(bpy)₃²⁺/Ni(cyclam)²⁺

CO₂ can be reduced using photogenerated reductants as shown in Figure 1. Photochemical CO₂ reduction has been reported in a catalytic system using Ru(bpy)₃²⁺ as the sensitizer, Ni(cyclam)²⁺ as the electron relay catalysts and ascorbate as a sacrificial reductive quencher (Table 5) [15, 16]. The quantum yield for CO production is ~10⁻⁴ at pH 4 with low selectivity for CO formation due to coproduction of H₂. The yields of both CO and H₂ are pH dependent. Without Ni(cyclam)²⁺, a system containing Ru(bpy)₃²⁺ and TEOA produces HCOO⁻ with a quantum yield of ~5 %, but no CO [38, 39]. In order to improve the CO yield, complexes that covalently link the sensitizer to the catalysts have been prepared. Complexes in which Ru(bpy)₃²⁺ or Ru(phen)₃²⁺ are bound to Ni(cyclam)²⁺ have been studied [40–43]. However, these supramolecular photochemical systems have low yields of CO due to competing processes in the quenching of the photoexcited complexes [40, 43]. Several pyridine derivatives of Ni(cyclam)²⁺, Ni(Pr-cyclam)²⁺, were prepared and used as catalysts together with Ru(bpy)₃²⁺. These systems produced up to five times more CO than the systems with underivatized Ni(cyclam)²⁺ [42].

Bismacrocylic nickel complexes, [Ni₂(bcyclam)]⁴⁺ and [Ni₂(bMe₂cyclam)]⁴⁺, have been prepared and tested as CO₂ reduction catalysts. The ligands bcyclam and bMe₂cyclam have two connected cyclam or dimethylcyclam units, respectively, as shown in Figure 2. While [Ni₂(bMe₂cyclam)]⁴⁺ shows good selectivity and a high yield for CO formation, [Ni₂(bcyclam)]⁴⁺ and the corresponding monomeric nickel complexes (Ni(cyclam)²⁺ and Ni(Me₂cyclam)²⁺) do not [44]. The authors attribute this to the configuration of the methyl groups, which occupy the axial positions of the six-membered chelate rings. However, why axial methyl groups increase the catalytic activity is not clear, since axial methyl groups normally hinder CO₂ binding.

Systems with *p*-terphenyl/CoL²⁺

Oligo(*p*-phenylene)s ranging from *p*-terphenyl (TP) to *p*-sexiphenyl sensitize the photoreduction of CO₂ to formic acid (Figure 5). The systems use triethylamine as a

Table 5. Photochemical CO₂ reduction with metal macrocycles.

^a Unless noted, otherwise the quantum yield of product formation is defined as the formation rate divided by the light intensity.^b With 15 % water in DMF.^c With 15 % water and excess bpy in DMF.^d Assuming Φ for Ni(cyclam)²⁺ is 0.001.

Figure 5. Schematic reaction mechanism for photochemical CO₂ reduction using TP and ML.

sacrificial electron donor in aprotic polar solvents such as DMF and MeCN [48, 49]. The photoreduction of CO₂ proceeds via electron transfer from the photo-generated anion radical of the *p*-phenylene directly to the CO₂ molecule. In the case of TP, the quantum yield of HCO₂⁻ formation is 3.6 % at 313 nm. Unfortunately, a photo-Birch reduction of the TP producing dihydroterphenyl derivatives occurs in parallel with the photoreduction process and photoactivity is quickly lost. The photodegradation is suppressed when metal macrocycles are added as electron mediators between the reduced terphenyl anion radical and the CO₂. Thus cobalt macrocycles mediate the photoreduction of CO₂ with TP and a tertiary amine (including the β -hydroxylated tertiary amine) as sacrificial electron donor in acetonitrile/methanol mixtures [17]. The system produces CO and formate efficiently with only small amounts of H₂. The combined quantum yield of CO and formate is 13 % at 313 nm in the presence of triethanolamine and Co(cyclam)³⁺.

Mechanistic and kinetic studies of the TEA–TP–CoHMD²⁺–CO₂ system have been undertaken [28] using flash photolysis techniques. In the absence of added CoHMD²⁺ and CO₂, the TP^{•-} spectrum was obtained in MeCN–MeOH, consistent with the reported rate constant for Eq. (14) of $3 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ in THF [49]; decay of TP^{•-} in MeCN–MeOH solution follows first-order kinetics with a rate constant of 400 s^{-1} .

The transient absorption spectrum of a sample with added Co^{II}HMD²⁺ indicates the formation of the reduced cobalt complex, Co^IHMD⁺ (Eq. 15) [32, 34, 50]. The cobalt(I) complex is fairly stable with a lifetime of $>1 \text{ s}$ under the experimental conditions (Figure 6, bottom). The decay of the TP^{•-} absorption and the growth of the Co^IHMD⁺ absorption are shown in Figure 6, top left and right, respectively. The observed rates for the decay of TP^{•-} and growth of Co^IHMD⁺ are the same. The magnitudes of the changes in absorbance at 470 and 685 nm establish that the stoichiometry of the formation of Co(I) from TP^{•-} is $1:1 \pm 0.2$. A plot of the observed first-order rate constant (k_{obsd}) for the decay of TP^{•-} is linear in

Figure 6. Top left: decay of $\text{TP}^{\bullet-}$ monitored at 470 nm. Top right: growth of $\text{Co}^{\text{I}}\text{HMD}^+$ monitored at 670 nm. Bottom: transient absorption spectrum of $\text{Co}^{\text{I}}\text{HMD}^+$ observed 6 μs after the excitation for a degassed sample containing 0.1 mM TP, 0.5 M TEA, 0.1 M TEAP and 1 mM $\text{Co}^{\text{II}}\text{HMD}^{2+}$ in MeCN–MeOH.

$[\text{Co}^{\text{II}}\text{HMD}^{2+}]$ and gives a second-order rate constant close to diffusion controlled as expected due to the reaction's large driving force (~ 1.1 V).

The dependence of the decay rate of $\text{TP}^{\bullet-}$ on $[\text{CO}_2]$, measured for solutions containing CO_2 with no cobalt macrocycle is not linear in CO_2 concentration [28]. A rate constant of $<10^6 \text{ M}^{-1} \text{ s}^{-1}$ is estimated for the $\text{TP}^{\bullet-}$ – CO_2 reaction. This sluggish rate constant is consistent with the large reorganization of the $\text{CO}_2/\text{CO}_2^-$ couple and modest driving force for the reaction (0.5 V). Under photocatalytic conditions (continuous photolysis) the $\text{TP}^{\bullet-}$ reacts much faster with the cobalt complex than with CO_2 and $>90\%$ the photochemically generated reducing equivalents are captured by the cobalt macrocycle.

When CO_2 is introduced into the photosystem, the lifetime of the $\text{Co}^{\text{I}}\text{HMD}^+$ changes dramatically [28]. The decay of $\text{Co}^{\text{I}}\text{HMD}^+$ is shown in Figure 7 (at 670 nm) and has a rate constant for CO_2 binding (Eq. 12) of $6.5 \times 10^4 \text{ s}^{-1}$. The observed rate constant for $\text{Co}^{\text{I}}\text{HMD}^+$ decay is linearly dependent on CO_2 concentration. The CO_2 binding rate constant (forward reaction in Eq. 12) is $1.7 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$. The decay of the $\text{Co}^{\text{I}}\text{HMD}^+$ under a CO_2 atmosphere results in a finite absorbance at long times (Figure 7). In addition, the transient spectra measured at 50, 25, 0 and -25°C indicate a mixture of the five- and six-coordinate CO_2 adducts, $\text{CoHMD}(\text{CO}_2)^+$ and $\text{S-CoHMD}(\text{CO}_2)^+$ (Eq. 13). Since the CO_2 adducts have no significant absorption at 670 nm (while $\text{Co}^{\text{I}}\text{HMD}^+$ does), the ratio of the

Figure 7. Transient decay curve of $\text{Co}^{\text{I}}\text{HMD}^+$ monitored at 670 nm for a sample containing 0.1 mM TP, 0.5 M TEA, 0.1 M TEAP, 1 mM $\text{Co}^{\text{II}}\text{HMD}^{2+}$ and 0.53 mM CO_2 in MeCN–MeOH.

total amount of cobalt– CO_2 complex, $[\text{Co}(\text{CO}_2)]_t$, to the unreacted complex, $[\text{CoHMD}^+]$, is given by the ratio of the change in the absorbance at 670 nm, $A_0 - A_\infty$, to the final absorbance at 670 nm (Figure 7). One can define an effective equilibrium constant

$$\begin{aligned} K_{\text{CO}_2} &= \frac{[\text{Co}(\text{CO}_2)]_t}{[\text{Co}^{\text{I}}\text{HMD}^+][\text{CO}_2]} \\ &= \frac{A_0 - A_\infty}{A_\infty [\text{CO}_2]} \end{aligned} \quad (17)$$

where $[\text{Co}(\text{CO}_2)]_t = [\text{CoHMD}(\text{CO}_2)^+] + [\text{S-CoHMD}(\text{CO}_2)^+]$ and A_∞ and A_0 are the absorbances at 670 nm at long times and at $t = 0$, respectively. The above assumes that the $\text{Co}^{\text{I}}\text{HMD}^+$ is rapidly formed, both $\text{Co}^{\text{I}}\text{HMD}^+$ and the CO_2 adduct are stable on the transient absorption time-scale, and only $\text{Co}^{\text{I}}\text{HMD}^+$ absorbs. When the CO_2 concentration is lowered, $A_0 - A_\infty$ is reduced and A_∞ increases. K_{CO_2} is calculated from Eq. 17 as $1.1 \times 10^4 \text{ M}^{-1}$ as shown in Table 4.

The equilibrium constant K_{CO_2} is also given by

$$K_{\text{CO}_2} = K_{12}(1 + K_{13}[\text{S}]) \quad (18)$$

where K_{12} and K_{13} are the equilibrium constants for Eqs. 12 and 13, respectively. Equilibrium studies in MeCN indicate that K_{12} and $K_{13}[\text{S}]$ are $1.2 \times 10^4 \text{ M}^{-1}$ and 0.17, respectively, for $\text{Co}^{\text{I}}\text{HMD}^+$ at 25 °C [19, 32, 34], yielding a value of $1.4 \times 10^4 \text{ M}^{-1}$ for K_{CO_2} . CO_2 binding rate constants determined by transient absorbance in MeCN–MeOH, by cyclic voltammetry in pure MeCN, and by pulse radiolysis in H_2O are all about $1.7 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$. The CO_2 binding constant obtained by transient methods is in good agreement with the value obtained from equilibrium methods [28]. These results also indicate that the CO formation proceeds via the

initial formation of a five-coordinate $\text{Co}^{\text{I}}\text{HMD}(\text{CO}_2)^+$ complex that quickly forms an equilibrium mixture with the six-coordinate complex, $[\text{S}-\text{Co}^{\text{III}}\text{HMD}(\text{CO}_2^{2-})]^+$. The production of CO in the photolysis solution probably proceeds by the subsequent reactions of $[\text{S}-\text{Co}^{\text{III}}\text{HMD}(\text{CO}_2^{2-})]^+$ shown in Eqs. 19 and 20:

The rate-determining step in the continuous photolysis system must be subsequent to the formation of the $\text{S}-\text{CoHMD}(\text{CO}_2)^+$ and is likely to be the C–O bond breakage in the bound carboxylic acid in Eq. 20. Recent developments in transient FTIR spectroscopy may allow the study of the reactions $\text{S}-\text{CoHMD}(\text{CO}_2)^+$ in the photocatalytic system.

Studies of catalytic systems with other cobalt macrocycles highlight some of the factors controlling the kinetics of the photoreduction of CO_2 [28]. Photogenerated $\text{Co}^{\text{I}}\text{DMD}^+$ (lifetime 16 μs) is unstable whereas $\text{Co}^{\text{I}}\text{OMD}^+$ is very stable (lifetime 6 h) in MeCN solution. The CO_2 binding constants (K_{CO_2}) are 6 and $>5 \times 10^4 \text{ M}^{-1}$ for $\text{Co}^{\text{I}}\text{OMD}^+$ and $\text{Co}^{\text{I}}\text{DMD}^+$, respectively, at room temperature. While the DMD complex with no axial methyl groups prefers the six-coordinate CO_2 adduct, formation of the six-coordinate $\text{S}-\text{CoOMD}(\text{CO}_2)^+$ is unfavorable owing to the steric hindrance of the four axial methyl groups. The $\text{Co}^{\text{II/I}}$ redox potentials, the CO_2 binding constants and the lifetimes show a strong correlation: $\text{Co}^{\text{I}}\text{OMD}^+$ (−1.28 V, 6 M^{-1} , 6 h), $\text{Co}^{\text{I}}\text{HMD}^+$ (−1.34 V, $1.2 \times 10^4 \text{ M}^{-1}$, ~2 s) and $\text{Co}^{\text{I}}\text{DMD}^+$ (−1.51 V, $>5 \times 10^4 \text{ M}^{-1}$, 16 μs).

Systems with phenazine/ CoL^{3+}

Recently photoreduction of CO_2 to HCOO^- (together with small amounts of CO and H_2) has been achieved by UV irradiation (313 nm) of a system involving phenazine as a photosensitizer, $\text{Co}(\text{cyclam})^{3+}$ as an electron mediator and TEA as an electron donor [47]. The quantum yield for the formation of HCOO^- is 0.035. Electron transfer from the photogenerated radical anion ($\text{Phena}^{\bullet-}$) to $\text{Co}(\text{cyclam})^{3+}$ ($k = 4.3 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$) results in the formation of $\text{Co}(\text{cyclam})^{2+}$. Since the reduction potential of $\text{Co}(\text{cyclam})^{2+/+}$ is ~−1.9 V vs. SCE in MeCN, $\text{Phena}^{\bullet-}$ (−1.18 V vs. SCE for a $\text{Phena}/\text{Phena}^{\bullet-}$ couple), unlike $\text{TP}^{\bullet-}$, is hardly capable of reducing $\text{Co}(\text{II})$ to $\text{Co}(\text{I})$. The authors suggest that PhenaH^{\bullet} , produced by the protonation to $\text{Phen}^{\bullet-}$, may transfer a hydrogen atom to $\text{Co}(\text{cyclam})^{2+}$ to form $\text{Co}(\text{cyclam})(\text{H})^{2+}$ and insertion of CO_2 into the hydride produces HCOO^- via the Co^{III} –formate complex. Although the results appear to support the proposed mechanism, the hydrogen-atom transfer step and the CO_2 insertion step have not been investigated in detail.

3.3 Re(α -diimine)(CO)₃X, Re(α -diimine)(CO)₂XX' and Similar Complexes

3.3.1 Overview of CO₂ Reduction System Mediated Rhenium Complexes

Complexes of the general formula *fac*-Re(α -diimine)(CO)₃X and Re(α -diimine)(CO)₂XX' (where α -diimine = bpy, phen, substituted bpy or phen, etc. and X, X' = halide, solvent, alkyl, benzyl, monodentate phosphine, CO, etc.), have attracted interest since the mid-1970s [51–53]. Many of these complexes show emission from their lowest long-lived MLCT state at room temperature in solution. Their catalytic properties for CO₂ reduction have also been investigated. Electrolysis of a solution containing *fac*-Re(bpy)(CO)₃Cl and 0.1 M Bu₄NPF₆ in freshly distilled CO₂-saturated MeCN at –1.5 V (vs. SCE) produces both CO and CO₃^{2–} with current efficiencies of 98 and 110 %, respectively [54]. Further, *fac*-Re(bpy)(CO)₃X (X = Cl[–], Br[–]) has been used successfully as a photocatalyst for CO₂ reduction to CO with TEOA in DMF [55–58]. When X = Cl[–], a quantum yield of 0.14 has been measured in the presence of excess Cl[–]. A formate–rhenium complex, *fac*-Re(bpy)(CO)₃(O₂CH), has been isolated in the absence of excess Cl[–].

Among rhenium catalysts for the photochemical reduction of CO₂, *fac*-Re(bpy)(CO)₃{P(OEt)₃}⁺ is the best catalyst and irradiation of DMF solutions containing CO₂ and TEOA yields CO with a quantum yield of 0.38 [59]. However, the formate complex *fac*-Re(bpy)(CO)₃(O₂CH) is also produced upon irradiation of Re(bpy)(CO)₃(PR₃)⁺ (R = O-*i*-Pr, OEt and Ph) in yields of 24, 73 and 55 %, respectively, based on *fac*-Re(bpy)(CO)₃(PR₃)⁺. It is generally believed that the formate complex is produced by CO₂ insertion into an Re–H bond and leads to the production of free formate. However, neither electrochemical nor photochemical CO₂ reduction using *fac*-Re(bpy)(CO)₃X produces any significant amount of free formate. Despite the great interest in CO₂ utilization, the mechanism of CO formation with *fac*-Re(bpy)(CO)₃X remains unclear. Below we discuss the possible involvement of intermediates such as Re–COO, Re–COOH, Re–CHO, Re–H, Re–CO, Re–O₂COH, Re–CH₂OH, etc. Some properties of the Re(α -diimine)(CO)₃X and Re(α -diimine)(CO)₂XX' complexes are summarized in Tables 6–8.

3.3.2 Properties of Re(α -diimine)(CO)₃X and Re(α -diimine)(CO)₂XX'

Redox properties

The complexes can be both oxidized and reduced; reduction potentials for many of the complexes are shown in Table 6. Cyclic voltammograms of Re(α -diimine)(CO)₃X show that in most cases the first oxidation is chemically irreversible at scan rates of 0.1–0.2 V s^{–1}; however, at much faster sweep rates (>100 V s^{–1}) a reversible wave is observed at 1.32 V (vs. SCE) in MeCN for Re(bpy)(CO)₃Cl [60]. The first oxidation is metal based and is followed by the rapid loss of carbon monoxide due to the weakening of the Re π -backbonding

to CO. Oxidation of *fac*-Re(bpy)(CO)₃H occurs more easily than that of *fac*-Re(bpy)(CO)₃Cl, indicating the increased electron density on the Re center.

The electrochemical behavior of Re(α -diimine)(CO)₃X in the negative potential region usually shows several reduction waves. The first reduction wave is reversible and is assigned as a ligand-based reduction. The second wave is usually irreversible and assigned as a metal-based reduction followed by the rapid loss of X.

Spectroelectrochemical experiments using FTIR indicate that the reduced *Re*(bpy)(CO)₃Cl^{•−} shows a significant shift of the CO vibrational frequencies to lower energy (see Table 8). The electron, while primarily residing in the bpy ligand π^* orbital, increases the amount of charge on the Re center by reducing Re–bpy π -backbonding. This increases Re–CO π -backbonding and raises the electron density in the π^* orbital of the CO, and thus decreases the CO bond strength and vibrational frequencies. The IR absorption of the CO, ν_{CO} , shifts by about 30 cm^{−1} to lower energy.

The stability of the reduced complex depends on the ability of the X ligand to accommodate the increased electron density of the Re center. In the case of ligands that cannot easily accept electron density into a low-energy orbital the increased electron density on the Re weakens the Re–X bond and can lead to loss of the X ligand. Complexes such as *Re*(dmb)(CO)₃Cl tend to form the five-coordinate radical [*Re*(dmb)(CO)₃][•] species upon reduction even in MeCN [61]. This effect is stronger in the doubly reduced species that has added an electron directly to the Re center.

Excited-state photochemistry and photophysics

The photophysical properties of low-spin d⁶ complexes, *fac-Re*(α -diimine)(CO)₃X, are summarized in Table 7. These complexes are often emissive in solution and generally have an intense MLCT absorptions [*Re*^I $d\pi \rightarrow \pi^*$ (α -diimine)] between 340 and 500 nm depending on the α -diimine, X ligands and the solvent [53, 65]. Changes in solvent polarity lead to pronounced shifts of the absorption maxima (e.g. 370 nm in MeCN to 400 nm in benzene for *Re*(bpy)(CO)₃Cl) as shown in Table 7 [52]). Modification of the α -diimine ligand also affects the MLCT absorption with the λ_{max} shifting to shorter wavelength in the order dmb < phen < bpy [52, 53]. The replacement of Cl[−] by I[−] changes the excited-state character from MLCT to XLCT (X = halide) [76]. The MLCT absorption of *Re*(bpy)(CO)₃X (X = H or CH₃) is red shifted compared with that of *Re*(bpy)(CO)₃Cl. An excellent review of the photophysics of these complexes by Stufken and Vlcek has recently been published [53].

For *fac-Re*(α -diimine)(CO)₃Cl the initial absorption at ~400 nm populates a short-lived ¹MLCT state. This state rapidly decays to the long-lived ³MLCT states. These states are actually three closely spaced levels split by spin–orbit coupling. Since the splitting is small the states behave kinetically as a single level at temperatures above 77 K [53]. The ³MLCT excited state can be viewed as a charge-separated species * [*Re*^{II}(α -diimine^{•−})(CO)₃Cl]. Transient UV–vis spectra show that the excited-state absorption corresponds to the α -diimine^{•−} anion chromophore [65]. Transient IR spectroscopy of the excited state shows a significant shift (20 to 80 cm^{−1}) of the CO vibrational frequencies to higher energy. The shift is similar to but smaller than that observed on oxidation of the *Re*(α -diimine)(CO)₃Cl complex [70]. The charge transfer in the excited state decreases the amount of charge on the Re center. This reduces the π -backbonding between the Re center and the CO ligands, thereby increasing the CO bond strength and vibrational frequencies. Similar effects have also been observed in the time-resolved resonance Raman spectroscopy [53].

The complexes often undergo radiative decay from their lowest excited state both in fluid solutions at room temperature and in glassy media at 77 K [51, 63, 64, 71]. Emission lifetimes are typically 20 ns to 2 μ s at room temperature and are summarized in Table 7. The excited state can decay by two nonradiative pathways: by internal conversion to the ground state and by a thermally activated process through a higher energy excited state that rapidly decays to the ground state. The exact parameters for the two pathways depend on X, L, solvent and temperature.

The ³MLCT excited state is both a strong oxidant and a strong reductant and it can be quenched by either electron acceptors (oxidative) or donors (reductive quenching) [65, 71]. Table 9 gives rate constants for oxidative and reductive quenching of the MLCT excited state of a number of *fac*-Re(α -diimine)(CO)₃X complexes.

The relationship between the absorption (E_{abs}), emission (E_{em}), reorganization (λ_r), the singlet–triplet splitting (E_{st}) energies [87] and the energy difference between the thermally relaxed excited and ground states (E_{0-0}) is shown in Figure 8 [88]. In the equation

$$E_{\text{abs}} = E_{\text{em}} + E_{\text{st}} + 2\lambda_r \quad (21)$$

the reorganization energy, λ_r , is generally broken into contributions from the solvent and/or low-frequency internal modes of the complex, λ_s , and from the internal high-frequency modes of the complex, λ_i , with the total reorganization energy given by $\lambda_r = \lambda_s + \lambda_i$. A spherical continuum model [89] can be used to estimate the solvent contribution to λ_s . Using this model [90], $\lambda_s = 0.18$ eV for Ru(bpy)₃^{2+/*} in H₂O and 0.33 and 0.22 eV for Re(bpy)(CO)₃Cl in H₂O and CH₂Cl₂, respectively. The larger value for the Re (vs the Ru) complex is due to its smaller size while the decrease in the value of λ_s on going from water to CH₂Cl₂ reflects the decrease in the polarity of the solvent.

An alternative method of estimating the reorganization energies involves spectral fitting of the emission [91, 92]. For a number of rhenium complexes the λ_s and λ_r values are given in Table 10. In general, similar λ_s values are estimated by either method with λ_s typically being about half of the total reorganization energy. As expected, the inner-shell reorganization energy for the Re carbonyl complexes is significant as indicated by the shifts in the ν_{CO} frequencies. E_{0-0} and the E_{st} are estimated for a number of complexes in Table 10. One notes that E_{st} is approximately constant for the Ru(bpy)(CO)₃Cl and Ru(phen)(CO)₃Cl complexes if one excludes the two nonpolar solvents. The excited state energies, E_{0-0} , are important since they can be used to estimate the redox potential of the excited state.

The reduction potentials for either the oxidation ($E_{1/2}^{+/*}$) or the reduction ($E_{1/2}^{*/-}$) of the excited state can be calculated from the ground-state potential and the excited-state energy, E_{0-0} , by

$$E_{1/2}^{*/-} = E_{0-0} + E_{1/2}^{0/-} \quad (22)$$

$$E_{1/2}^{+/*} = E_{1/2}^{+/0} - E_{0-0} \quad (23)$$

The reduction potentials for the $\text{Re}(\text{phen})(\text{CO})_3\text{Cl}^+/\text{*Re}(\text{phen})(\text{CO})_3\text{Cl}$ and $\text{*Re}(\text{phen})(\text{CO})_3\text{Cl}/\text{Re}(\text{phen})(\text{CO})_3\text{Cl}^-$ couples have been estimated [71] to be approximately -1.0 and $+1.0$ V (vs. SCE in MeCN), respectively, using an excited-state energy of ~ 2.3 eV. Using the estimates in Table 10 one obtains -1.2 and $+1.2$ V. The data in Tables 6 and 10 allow redox potentials for a number of other complexes to be calculated.

Visible light irradiation of an Re-alkyl complex, $[\text{Re}(\text{dmb})(\text{CO})_3\text{R}]$ ($\text{R} = \text{CH}_3$, Et, *i*Pr, or Bz; dmb = 4,4'-dimethyl-2,2'-bipyridine), gives rise to a homolytic cleavage of the Re–R bond with the formation of the radicals $[\text{Re}(\text{dmb})(\text{CO})_3]^{\cdot}$ and R^{\cdot} [78]. The reaction proceeds with a quantum efficiency of 0.4 for $\text{R} = \text{CH}_3$ and 1 for $\text{R} = \text{Et}$, *i*Pr or Bz. The time-resolved UV–vis and IR absorption spectra reveal that for $\text{Re}(\text{dmb})(\text{CO})_3(\text{CH}_3)$ the initially formed excited

state is a ¹MLCT state. The ¹MLCT state can either pass over a thermal barrier of 1560 cm⁻¹ to the dissociative ³ $\sigma\pi^*$ state (and decompose into radicals) or decay nonradiatively to the ³MLCT state. In the case of R = Et, *i*Pr or Bz, the dissociative pathway to form the radical dominates. In all cases the radicals form in less than 10 ns.

Formate–rhenium complexes

fac-Re(bpy)(CO)₃H undergoes a thermally activated reaction with CO₂ in organic solvents to produce the stable formate adduct, *fac*-Re(bpy)(CO)₃(O₂CH) [98]. The rate of formation is first order in [CO₂] and [Re] with a rate constant of $2.0 \times 10^{-4} \text{ M}^{-1} \text{ s}^{-1}$ in THF and $2.7 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ in MeCN. Kinetic studies using *fac*-Re(bpy)(CO)₃D reveals an inverse $k_{\text{H}}/k_{\text{D}}$ isotope effect of ~ 0.5 for both solvents. The reaction occurs by associative hydride-transfer. While the thermal reaction is very slow at room temperature, irradiation with 436 nm light increases the rate by a factor of more than 10 [66]. While the CO₂ insertion into the Re–H bond reduces the CO₂, the authors do not report CO or formate production. Nor is formate a product in photochemical CO₂ reduction systems that utilize *fac*-Re(bpy)(CO)₃X [56–58, 77], although the presence of Re(bpy)(CO)₃(O₂CH) was identified in such systems.

Re–CO₂ and Re–COOH complexes

Metallocarboxylates and metallocarboxylic acids are proposed as intermediates in photocatalytic reduction of CO₂ by *fac*-Re(α -diimine)(CO)₃X, but have not been directly observed in the photocatalytic systems. Re(dmb)(CO)₃(COOH), Re(bpy)(CO)₃(CH₂OH) and (CO)₃(dmb)Re–C(O)–O–Re(dmb)(CO)₃ have been prepared by different routes and characterized [83, 84]. Reaction of Re(dmb)(CO)₄(Otf) with aqueous KOH in water produces *fac*-Re(dmb)(CO)₃(COOH) as a yellow precipitate. This complex has IR carboxylate absorptions, ν_{OCO} , at 1572 and 1194 cm⁻¹, which are at lower energy than those of the ruthenium analog, [Ru(bpy)₂(CO)(COOH)]⁺ (1618 and 1240 cm⁻¹). The ruthenium complex has been prepared by a similar reaction [Ru(bpy)₂(CO)₂²⁺ with OH⁻] and characterized by X-ray crystal structure determination [99]. Reaction of Re(bpy)(CO)₄(Otf) with NaBH₄ in methanol leads to the formation of the red Re(bpy)(CO)₃(CH₂OH). Irradiation of Re(bpy)(CO)₃(CH₂OH) in dry MeOH yields a red solid, *fac*-Re(bpy)(CO)₃(OMe), in 97 % yield [83]. The authors suggest that a β -elimination converts Re–CH₂OH to Re–H, which upon photolysis reacts with MeOH to form Re–OMe.

The μ^2 – η^2 -CO₂-bridged complex (CO)₃(dmb)Re–C(O)–O–Re(dmb)(CO)₃ is isolated (together with several unidentified species) on standing from an acetone solution of *fac*-Re(dmb)(CO)₃(COOH). Their IR data are summarized in Table 8. Neither *fac*-Re(dmb)(CO)₃(O₂CH) nor *fac*-Re(dmb)(CO)₃(H) has been observed as a product in the decomposition of *fac*-Re(dmb)(CO)₃(COOH) [84]. However, *fac*-Re(dmb)(CO)₃(COOH) in DMSO containing small amounts of water is transformed into the bicarbonato complex, *fac*-Re(dmb)(CO)₃(OC(O)OH) [100]. The detail mechanisms involving these species need to be elucidated.

3.3.3 Electrochemical Systems: One- and Two-electron Pathways

Extensive electrochemical studies on *fac*-Re(bpy)(CO)₃Cl in MeCN, THF or DMF indicate that reduction of *fac*-Re(bpy)(CO)₃Cl gives the radical anion, Re(bpy)(CO)₃Cl^{•−}, which reacts with CO₂ after loss of chloride. As shown in Figure 9, CO₂ reduction is proposed [54, 61, 63] to occur by two independent routes, a 1e pathway via Re(bpy)(CO)₃[•] and a 2e pathway via Re(bpy)(CO)₃[−]. FTIR studies of Re(bpy)(CO)₃Cl^{•−} (ν_{CO} 1996, 1883, 1868 cm^{−1}) indicate that it is in equilibrium with Re(bpy)(CO)₃(solvent)[•] (ν_{CO} 2011, 1895 cm^{−1}) and [Re(bpy)(CO)₃]₂ (ν_{CO} 1988, 1951, 1887, 1859 cm^{−1}) in MeCN. Unfortunately, the equilibrium constants and the rate constant for Cl[−] loss from Re(bpy)(CO)₃Cl^{•−} have not been determined. Reduction of Re(bpy)(CO)₃(MeCN)⁺ in THF leads to the formation of three species: Re(bpy)(CO)₃(MeCN)[•], Re(bpy)(CO)₃(THF)⁺ and [Re(bpy)(CO)₃]₂. Re(bpy)(CO)₃(THF)[•] is not observed even in the reduction of Re(bpy)(CO)₃(Otf) in THF. Thus Re(bpy)(CO)₃(THF)[•] is unstable and rapidly dimerizes after loss of THF.

IR spectral changes during the further reduction of Re(bpy)(CO)₃Cl^{•−} indicate rapid loss of a Cl[−] ligand with formation of [Re(bpy)(CO)₃][−]. The further reduction of either [Re(bpy)(CO)₃(solvent)][•] or [Re(bpy)(CO)₃]₂ also yields [Re(bpy)(CO)₃][−]. This illustrates the instability of non- π -backbonding ligands coordinated to the formally Re⁰ center.

IR spectral changes of Re(bpy)(CO)₃Cl (with excess Cl[−]) or Re(bpy)(CO)₃(Otf) (without excess Cl[−]) in electrochemical reduction in THF under a CO₂ atmosphere indicate the disappearance of Re(bpy)(CO)₃X (X = Cl or Otf) and the formation of [Re(bpy)(CO)₃(O₂CH)]^{•−} (ν_{COO} 1628 cm^{−1}), CO₃^{2−} (ν_{COO} 1643 cm^{−1}), CO and an unidentified species with ν_{COO} at 1680 cm^{−1} (carboxylate?) [61]. It is reported that the ν_{COO} band of Re(bpy)(CO)₃(O₂CH) and [Re(bpy)(CO)₃(O₂CH)]^{•−} are coincident (see Table 8). IR spectral changes of Re(bpy)(CO)₃Cl in MeCN with excess Cl[−] under a CO₂ atmosphere have been reported to illustrate rapid formation of free CO₃^{2−} (ν_{COO} 1643 cm^{−1}) and CO, together with an unassigned product having ν_{COO} at 1679 cm^{−1}. The unassigned product appears before formation of CO₃^{2−}. The IR spectrum in the ν_{CO} region shows only small amounts of [Re(bpy)(CO)₃Cl]^{•−} and [Re(bpy)(CO)₃(MeCN)][•] compared with the parent Re(bpy)(CO)₃Cl and free CO₃^{2−}, indicative of the catalytic nature of CO₃^{2−} production. Both [Re(bpy)(CO)₃][•] (1e pathway) and [Re(bpy)(CO)₃][−] (2e pathway) are alleged to react with CO₂.

The authors suggest a modification of the original mechanism shown in Figure 9 [61]. In this mechanism, shown in Figure 10, the actual catalytic species is Re(bpy)(CO)₃S[•], i.e., the one-electron reduced species that has had X replaced by a solvent molecule. This species is formed from the original Re(bpy)(CO)₃Xⁿ⁺ upon one-electron reduction. It is asserted that the electron density on the Re center is of critical importance in the catalytic scheme. The Re center must be sufficiently electronically poor to allow coordination of Lewis bases such as phosphines or MeCN otherwise rapid dimerization will occur. The use of a slightly coordinating solvent or free Cl[−] in solution helps to suppress this reaction. Alternatively, the Re center must be electronically rich enough to coordinate and reduce CO₂.

Figure 9. One- and two-electron pathways for CO_2 reduction. A = an oxide ion acceptor.

Figure 10. Modified one- and two-electron pathways for CO_2 reduction. S = solvent molecule.

The main products observed, CO and CO₃²⁻, are produced by both pathways. The authors assert [61] that production of the major side product Re(bpy)(CO)₃(O₂CH) (ν_{COO} 1630 cm⁻¹) is suppressed when the two-electron pathway dominates as it does when using [Re(bpy)(CO)₃{P(OEt)₃}]⁺ or Re(bpy)(CO)₃Cl in MeCN. They assume that Re(bpy)(CO)₃(O₂CH) is produced from either [Re(bpy)(CO)₃(CO₂)][•] or [Re(bpy)(CO)₃(CO₂)]⁻ by addition of e⁻ and H⁺ or H⁺, respectively. However, such transformations to metal-formate complexes are not well characterized. Rhenium carboxylates, [Re(bpy)(CO)₃(COO)] and [Re(bpy)(CO)₃(COO)]⁻, are generally proposed [5] as intermediates in the electrochemical reduction of CO₂ to CO (and CO₃²⁻) but no direct spectroscopic evidence has been obtained. Reported IR spectra involving an unidentified species, with ν_{COO} at 1680 cm⁻¹, show a relatively intense ν_{COO} band compared with the ν_{CO} bands. Normally, the molar absorptivity of the ν_{CO} band for bound CO is typically 3–5 times larger than that for bound CO₂ [19, 101, 102]. The correct identification of this species, which may be an organic carbonate, is essential.

3.3.4 Photochemical Systems

Re(α -diimine)(CO)₃X (X = halide, solvent, monodentate phosphine ligand, etc.) has been used as a photocatalyst for CO₂ reduction with TEOA in DMF [55–59, 72, 77] (Table 11). The ³MLCT excited states of these Re complexes are reductively quenched by TEOA (TEOA^{+/0} potential \approx 0.8 V) [52] to form

Table 11. Photocatalytic reduction of CO₂ with Re(bpy)(CO)₃X in DMF with TEOA as an electron donor.

Sensitizer	Additive	Product	Φ (mol einstein ⁻¹) ^b	Ref.
[Re(bpy)(CO) ₃ Cl]	Cl ⁻	CO	0.14	55, 56
[Re(bpy)(CO) ₃ Br]		CO	0.13	57, 58
[Re(bpy)(CO) ₃ Br]	10 % H ₂ O	CO	0.079	58
[Re(bpy)(CO) ₃ Br]	20 % EtOH	CO	0.11	58
[Re(bpy)(CO) ₃ Br]	Br ⁻	CO	0.14	58
[Re(bpy)(CO) ₃ P(OEt) ₃] ⁺		CO	0.38	59
[Re(bpy)(CO) ₃ P(OEt) ₃] ⁺		CO	0.16	72
[Re(bpy)(CO) ₂ {P(OEt) ₃ } ₂] ⁺		CO		69
[Re(bpy)(CO) ₃ (PPh ₃)] ⁺		CO	0.05	77
[Re(bpy)(CO) ₃ (PEt ₃)] ⁺		CO	0.024	72
[Re(bpy)(CO) ₃ {P(n-Bu) ₃ }] ⁺		CO	0.013	72

[Re{(CF ₃) ₂ bpy}(CO) ₃ {P(OEt) ₃ }] ⁺		CO	0.005	72

[Re^I(bpy⁻)(CO)₃X]^{*}. Transient spectroscopy shows the expected bpy⁻ radical UV-vis absorption and ESR signals. When X = Br⁻, Cl⁻ or P(OEt)₃, the quenching rate constants are $6 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ [57], $8 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ [65] and $1.1 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ [72], respectively, in MeCN or DMF. Transient IR spectra of both the ³MLCT excited state and the radical anion for Re(bpy)(CO)₃Cl [81], Re(4,4'-bpy)₂(CO)₃Cl [80], Re(4,4'-bpy)₂(CO)₃(MeCN)⁺ [79], Re(bpy)(CO)₂{P(OEt)₃}₂⁺ [69], Re(bpy)(CO)₃(MeCN)⁺ [85, 79], Re(dmb)(CO)₃(MeCN)⁺ [79] and Re(dmb)(CO)₃(CH₃) [78] have been measured. Transient IR shows the expected shifts of ν_{CO} for both the excited state to higher (20–80 cm⁻¹) and the reduced species to lower energy (–15 to –40 cm⁻¹) [74, 79–81] (see Table 8).

The subsequent reactions of the radical species depend on the nature of α -diimine, X, solvent and electron donor as also found in the electrochemical studies. The mechanism for photochemical CO₂ reduction must account for reactions of the electron donor (e.g., TEOA or TEA) and its reaction products. TEOA or TEA can coordinate to metal complexes and change their redox properties [27]. The following reactions can all become important under different conditions:

Both electrochemical and photochemical reduction of Re(bpy)(CO)₃X (X = halide), yield [Re(bpy)(CO)₃X]^{•-} [54]. It has been suggested that [Re(bpy)(CO)₃X]^{•-} reacts directly with CO₂ after loss of a CO [56]; however, electrochemical results [54, 61] indicate that CO₂ attachment only takes place after loss of X⁻. The labilization of X⁻ produces either a five-coordinate [Re(bpy)(CO)₃][•] or the six-coordinate [Re(bpy)(CO)₃S][•]. The five-coordinate species can dimerize but under photolysis conditions their low concentration makes this reaction slow. The intermediates may react with CO₂ or pick up a second electron and a proton to give Re(bpy)(CO)₃H. The formation of Re(bpy)(CO)₃H and Re(bpy)(CO)₃(O₂CH) has been reported for Re(bpy)(CO)₃X (X = Cl and Br) systems [38, 54, 55, 57, 58, 66].

Whereas formate complexes generally produce formate, metal carboxylates (or metal CO₂ adducts) generally lead to CO production [5]. Hawecker et al. [56] concluded that the Re(bpy)(CO)₃(O₂CH) is a side-product and an unlikely intermediate in the photochemical CO production. Re(bpy)(CO)₃(O₂CH) is only half as active as a CO₂ photoreduction catalysts than Re(bpy)(CO)₃(Cl). Re(bpy)(CO)₃(O₂CH) production is suppressed in the presence of excess Cl[−] whereas in the absence of excess Cl[−] ion Re(bpy)(CO)₃(O₂CH) accumulates. Further, Re(bpy)(CO)₃(O₂CH) is also formed as a side-product in the electrochemical reduction [61].

Re(bpy)(CO)₃{P(OEt)₃}⁺ produces CO with the highest quantum yield of up to 0.38 [59]. The quantum yield and turnover number using Re(bpy)(CO)₃{P(OEt)₃}⁺ depend on the intensity and wavelength of the exciting light; however, for Re(bpy)(CO)₃Cl neither quantum yield nor turnover number is intensity and wavelength dependent. Since the lifetime of [Re(bpy)(CO)₃{P(OEt)₃}][•] (514 s) is much longer than that of [Re(bpy)(CO)₃Cl][•] (6 s) under Ar in DMF, an inner filter effect by [Re(bpy)(CO)₃{P(OEt)₃}][•] may explain the wavelength and intensity dependence [59].

Electrochemical studies indicate that [Re(bpy)(CO)₃{P(OEt)₃}][•] is very stable and does not lose P(OEt)₃ or react with CO₂ in THF [61]. Only on further reduction does the complex lose P(OEt)₃ to form the five-coordinate anion [Re(bpy)(CO)₃][−] which can react with CO₂. The first and second reduction potentials of Re(bpy)(CO)₃{P(OEt)₃}⁺ are reported to be −1.25 and ∼−1.9 V vs. SCE in MeCN [61, 67], assuming the Fc/Fc⁺ and Ag/AgNO₃ potentials are 0.38 and 0.33 V vs. SCE, respectively. The *E*_{0−0} of the ³MLCT state of the Re(bpy)(CO)₃{P(OEt)₃}⁺ is ∼2.8 eV (Table 10), thus the excited-state reduction potential is ∼1.5 V (*E*_{1/2}^{+ / 0} = −1.25 V vs. SCE). Therefore the quenching of the *Re(bpy)(CO)₃{P(OEt)₃}⁺ by TEOA (*E*_{1/2}^{+ / 0} = 0.6 V vs. SCE [103]) has Δ*E*⁰ ≈ 0.9 = (1.5 − 0.6) V.

The TEOA^{•+} radical, (HOCH₂CH₂)₃N^{•+}, can react with another TEOA to form the carbon radical (HOCH₂CH₂)₂NC[•]HCH₂OH as shown in Eq. 35.

Although (HOCH₂CH₂)₂NC[•]HCH₂OH is known to be a strong reducing agent, its potential is not known. The reduction potentials of TEA^{•+} and TEOA^{•+} are 0.96 [104] and 0.6 V [103] vs. SCE in MeCN, respectively. Thus TEOA, with its electronegative oxygens, is a better reducing agent than TEA. The reduction potential of Et₂N⁺=CHCH₃ (Eq. 38) has been measured to be −1.12 V vs. SCE in MeCN [105], so the potential of (HOCH₂CH₂)₂N⁺=CHCH₂OH (Eq. 36) will be more negative than −1.12 V. Thus, while (HOCH₂CH₂)₂N⁺=CHCH₂OH may re-

duce $\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}$ ($E_{1/2} = -1.35$ V) and $[\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}]^+$ ($E_{1/2} = -1.25$ V), it is not expected to reduce $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]^*$ ($E_{1/2} \approx -1.7$ V) or $[\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}]^*$ ($E_{1/2} \approx -1.9$ V). The above suggests that while the doubly reduced $[\text{Re}(\text{bpy})(\text{CO})_3]^-$ is formed in the electrochemical system, its formation is not possible in the photochemical system. Since $[\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}]^*$ does not lose $\text{P}(\text{OEt})_3$ [59], it is hard to understand how the singly reduced Re complex can acquire a CO_2 ligand.

Koike et al. assumed that the monoreduced $[\text{Re}(\text{bpy})(\text{CO})_3(\text{PR}_3)]^*$ reacts with CO_2 or dimerizes in the photochemical system that they studied [72]. From the decay of $[\text{Re}(\text{bpy})(\text{CO})_3(\text{PR}_3)]^*$ observed during continuous photolysis under CO_2 , the CO_2 binding rate constants have been estimated: $\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}$, $8.8 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$ [59]; $\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}$, $5.6 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$ [72]; $\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{O}-i\text{Pr})_3\}$, $9.4 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$ [72]; $\text{Re}(\text{dmb})(\text{CO})_3\{\text{P}(\text{OEt})_3\}$, $18.6 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$ [72]. These CO_2 binding rate constants are very slow compared with those of other metal complexes that act as photocatalysts: CoHMD^+ , $1.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ [28]; $\text{Ni}(\text{cyclam})^+$, $3.2 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ [24]; $\text{Pd}(\text{etpC})(\text{DMF})^+$, $53 \text{ M}^{-1} \text{ s}^{-1}$ [106]. The authors did not detect the formation of either the Re dimer or the CO_2 complex. Since they did not measure the dependence of the CO_2 binding rate on Re or CO_2 concentration, the actual pathway in the photochemical system is probably more complicated. Thus of fundamental importance in understanding photochemical CO_2 fixation is the elucidation of the mechanism that allows the singly reduced Re complex to bind CO_2 . One interesting possibility is that the reduced Re complex is photolabile and that the absorption of a second photon assists the loss of the sixth ligand. Detailed studies of the $\text{Re}(\text{bpy})(\text{CO})_3\text{X}$ ($\text{X} = \text{Cl}$ and Br) photochemical systems that report formation of $\text{Re}(\text{bpy})(\text{CO})_3\text{H}$, $\text{Re}(\text{bpy})(\text{CO})_3(\text{O}_2\text{CH})$ and $\text{Re}(\text{Mebpy})(\text{CO})_3\text{Br}$ in addition to the dimer [38, 54, 55, 57, 58, 66, 107] are needed.

3.4 Conclusions

Artificial photosynthetic systems offer the possibility of producing fuels and chemicals from CO_2 and sunlight in fewer steps and/or faster rates than in natural systems. It may also be possible to design such systems to operate under conditions and in environments where plant growth is not optimal or practical. Light capture, electron transfer and catalysis must be efficiently coupled. However, the approaches described in this chapter have several problems. All the systems require a sacrificial reagent. The stability of the systems is limited, the catalytic activities are too low and the overall costs are too high for commercialization. Dark reactions including the bond formation and cleavage steps are relatively slow. It is very important to investigate the factors controlling reaction rates and efficiencies through kinetic and mechanistic studies. At this stage, many questions remain. Hopefully, the insight obtained from a fundamental studies of the reactions occurring in the above systems

will provide the knowledge required for the design of useful systems. One fundamental and formidable challenge is the replacement of the 'sacrificial' electron donors by species that will lead to useful (or benign) chemicals in their own right.

Acknowledgments

We thank Drs. Norman Sutin and David Thompson (BNL) and Prof. Osamu Ishitani (Saitama University, Japan) for their helpful comments, and Prof. Shoichi Kita (Hirosaki University, Japan) for providing his unpublished data obtained during his stay at BNL. Brookhaven National Laboratory is funded under contract DE-AC02-98CH10886 with the US Department of Energy and supported by its Division of Chemical Sciences, Office of Basic Energy Sciences.

90. The spherical cavity model requires parameters for the solvent and the cavity to calculate the reorganization energy. The dimensions of the molecule have been obtained from models created in MacSparten. The cavity radius was calculated as $r = (\sqrt[3]{d_1 d_2 d_3})/2$, where d_i are the three principle diameters of the molecule (including van der Waals end radius for each atom) and are 7.8, 11.26 and 11.26, respectively, with $r = 5.0$ Å. The Re atom is placed off center by 1.3 Å and the electron transfer distance is 3.5 Å. The optical (square of the refractive index) and static dielectric constants of the solvent were used.

4 The Electrochemical and Photochemical Activation of Redox Enzymes

Eugenii Katz, Andrew N. Shipway and Itamar Willner

4.1 Introduction

In the great majority of enzymes the redox center is located sufficiently far from the outermost surface to be electrically inaccessible. Consequently, most enzymes do not exchange electrons with electrodes on which they are adsorbed, i.e., their redox centers are neither electrooxidized nor electroreduced upon the application of potentials that are more positive or negative than the thermodynamic redox potential of the enzyme redox center [1]. It seems that part of the protein or glycoprotein shell serves as an insulator to prevent indiscriminate electron exchange between the different redox macromolecules of living systems. This isolation is necessary because such exchange would lead to an equipotential system, unable to sustain life. The distance dependence of the rate of electron transfer in proteins has been the subject of extensive experimental [2] and theoretical studies [3] during the past two decades.

Electron-transfer theory predicts that the electron-transfer rate constant between a donor-acceptor pair is given by Eq. 1:

$$k_{\text{et}} \propto e^{-\beta(d-d_0)} e^{[-(\Delta G^\circ + \lambda)^2 / (4RT\lambda)]} \quad (1)$$

where ΔG° and λ correspond to the free energy and reorganization energy accompanying electron-transfer and d_0 and d are the Van der Waals distance and actual distance separating the donor-acceptor centers, respectively. The electrode and the redox center embedded in the enzyme can be viewed as a donor-acceptor pair. Thus, the thick protein layer surrounding the active center introduces a spatial separation of the donor-acceptor pair and a kinetic barrier for electron transfer. This separation leads to the electrical insulation of the active sites of most redox proteins/enzymes. Various approaches have been developed and many bioelectrochemical systems have been designed to overcome this problem, providing efficient electrical contact of biocatalysts at electrode surfaces. These methodologies range from the simple application of soluble enzymes with diffusional electron-hole mediators to

systems with very sophisticated biomolecular architectures composed of numerous components. In addition to the electrochemical activation of biocatalytic systems, enzymes may be activated by light in artificial systems composed of the biocatalyst and a photosensitizer together with some additional components providing efficient interaction between them. The aim of this chapter is to review different kinds of systems where redox enzymes are activated either by electrical contact with electrodes or by light, and to address the potential applications of such assemblies.

4.2 The Electrochemical Activation of Enzymes

4.2.1 Direct, Nonmediated Electron Transfer Between Enzymes and Electrodes

The direct electron transfer between the redox-active sites of proteins and electrodes is normally prohibited as a consequence of steric insulation by the protein matrix. Early studies demonstrated, however, that certain enzymes or redox proteins can exhibit electrical communication with electrode supports, and that electrically stimulated biocatalytic transformations can be driven by that process (Figure 1A)

Figure 1. The direct, non-mediated electrical contacting of enzymes: (A) direct electron transfer between an electrode and an enzyme molecule located in close vicinity to the surface; (B) application of the direct electrical 'wiring' of HRP for the detection of H_2O_2 produced by an oxidase in response to a primary substrate.

[4, 5]. The direct electroreduction of H_2O_2 by horseradish peroxidase (HRP):

has been demonstrated [6], and related heme-containing peroxidases, e.g., cytochrome *c* peroxidase [7], lactoperoxidase [8] and chloroperoxidase [9], have shown similar direct electron-transfer communication with electrode surfaces. Laccase (Lac, a copper-containing polyphenol oxidase) has been found to electrocatalyze the reduction of molecular oxygen [10]:

The ability of these enzymes to contact directly the electrode is attributed to the peripheral location of the redox center. A detailed kinetic study [11] of the peroxidase-catalyzed reduction of H_2O_2 revealed that 42 % of the enzyme molecules are aligned on the electrode surface in a configuration where the redox heme site is accessible for direct electron transfer. Other enzymes possess two redox sites, and electron transfer proceeds vectorially from a peripheral site to an inner component. For example, *p*-cresol methyl hydroxylase [PCMH, a flavin adenine dinucleotide (FAD)- and heme-containing redox enzyme] affects the direct oxidation of *p*-cresol to *p*-hydroxybenzaldehyde [12]:

Similarly, flavocytochrome c_{552} (Cyt c_{552} , sulfide cytochrome *c* oxidoreductase), that includes FAD and two covalently linked heme groups, is bioelectrocatalytically active for the oxidation of sulfide to sulfur [13]:

The direct electronic communication of this series of redox enzymes allows their application as bioactive sensing interfaces: *p*-cresol [12], methylamine [14] and fructose [15] detection have been reported in the presence of *p*-cresol methyl hydroxylase, methylamine dehydrogenase and fructose dehydrogenase, respectively.

Sensors have also been constructed from some oxidases directly contacted to electrodes to give bioelectrocatalytic systems. These enzymes utilize molecular oxygen as the electron acceptor for the oxidation of their substrates. Enzymes such as catechol oxidase, amino acid oxidase, glucose oxidase, lactate oxidase, pyruvate oxidase, alcohol oxidase, xanthine oxidase and cholesterol oxidase catalyze the oxidation of their respective substrates with the concomitant reduction of O_2 to H_2O_2 :

The direct electron-transfer communication between HRP and electrodes allows the electroreduction of H_2O_2 in the potential range -0.2 to 0 V (vs. SCE) and its coupling to these oxidases can thus yield amperometric biosensors (Figure 1B). The

quantity of H_2O_2 generated is controlled by the substrate concentration, so the resulting current provides a quantitative measure for the analyte. Thus, amperometric biosensors based on HRP coupled with glucose oxidase for glucose analysis [16–20], with alcohol oxidase for alcohol detection [21], with choline oxidase for choline analysis [16] and with amino acid oxidase for amino acid determinations [22] have been constructed. Various conducting materials such as carbon black [6], pyrolytic graphite [23] and platinized carbon particles [24] have been used to support the enzymes, and carbon paste [25, 26] and polypyrrole [17, 25] have been used to entrap them.

Electrodes functionalized with some low molecular weight electrochemically inactive compounds have been found to effect electrical communication between redox proteins or redox enzymes and electrode supports. Reversible electrochemistry of Cyt *c*, which includes a partially exposed heme site, has been observed at Au, Pt and Ag electrodes modified with monolayers of various promoters [27–29]. Generally these promoters are linked to the electrode by a thiol or disulfide group and include an organic functional unit that interacts with the Cyt *c* protein backbone. The promoter monolayer prohibits the direct contact between the protein and the metal electrode surface, thus preventing irreversible unfolding of the protein. In addition, interactions between the promoter and the protein molecules can result in the specific alignment of the protein at the electrode surface, providing short electron-transfer distances that allow efficient electrical contact. The most common promoter for the activation of the interfacial electrochemistry of Cyt *c* is bis(4-pyridyl) disulfide [30], but several other thiol- or disulfide-derivatized molecules are also effective [31]. Amino acid and oligopeptide monolayers have been used as promoters for enhancing the interfacial electrochemistry of Cyt *c* [32] as well as other cytochromes [33]. Other promoters such as imidazole [34], thiophene [35] and iodide [36] deposited on Au or Ag electrodes have also been used to facilitate Cyt *c* electrochemistry. This electrochemically contacted Cyt *c* was applied to activate secondary biocatalytic processes stimulated by Cyt *c*-dependent enzymes (e.g., cytochrome oxidase, cytochrome reductase, ascorbate oxidase, laccase, etc.) [37, 38]. A similar methodology has been applied to other redox proteins and enzymes such as ferritin, blue copper proteins, azurin, pseudoazurin, umecyanin, stellacyanin, plantacyanin, plastocyanin and cucumber ascorbate oxidase [39]. 4-Mercaptopyridine (and other thiol and disulfide derivative) monolayer-modified Au electrodes have been used to enhance the electrochemistry of these proteins/enzymes. Protonated aminosiloxane-modified indium tin oxide electrodes have been reported to be efficient interfaces for stimulating electron transfer to negatively charged ferredoxin [40]. These promoters apparently align the protein molecules on the electrode surface in an orientation that facilitates efficient electron-transfer communication.

Direct electrical communication between enzyme active sites and electrodes may also be facilitated by the nanoscale morphology of the electrode. The modification of electrodes with metal nanoparticles allows the tailoring of surfaces with features that can penetrate close enough to the enzyme active site to make non-mediated electron transfer possible. Electrodes modified by unaggregated 12 nm diameter gold nanoparticles have been found to have the correct morphology to allow direct electron transfer between the cytochrome *c* active site and the electrode [41]. Elec-

trodes modified by different sizes or aggregation states of gold colloids do not exhibit this behavior. The electrical contacting of enzymes via Au nanoparticles has also been used for the construction of biosensing devices. In one example, 30 nm particles were used to establish efficient contact with HRP [42], and in another, a D-fructose dehydrogenase–Au colloid complex was immobilized on an electrode in a carbon paste [43].

Although enzymes with deeply embedded active centers do not normally allow significant non-mediated electron transfer [44], under carefully chosen conditions direct electron transfer is possible, and has been reported for glucose oxidase (GOx) at a bare Ag electrode [45] and in graphite paste electrodes [46]. These systems are unusual and the nonmediated mechanism of such long-range electron transfer is not fully understood.

Another way to effect direct electron transfer to the active sites of proteins is to shorten the electron-transfer distance by employing low molecular weight redox-active fragments of the native biomaterials. Microperoxidase-11 (MP-11, **1**), is a heme undecapeptide constituting the active site microenvironment of Cyt *c* [47]. Since the active site of MP-11 is not sufficiently isolated by the short oligopeptide chain, the direct electrochemistry of MP-11 can be observed in aqueous [48] and nonaqueous [49] solutions at unmodified electrodes. Microperoxidase-11 has been covalently linked to amino- [50] and carboxyl-functionalized [51] Au electrodes by its carboxylic and amino groups, respectively. The MP-11 monolayer reveals electrocatalytic activity for the reduction of H_2O_2 [50] in aqueous media and for organic peroxide reduction in nonaqueous solutions [52].

4.2.2 Electron Transfer Between Enzymes and Electrodes Provided by Diffusional Mediators

The electrical contacting of redox enzymes that defy direct electrical communication with electrodes can be established by mediated electron transfer using synthetic or biologically active charge carriers. Mediated electron transfer (MET) can be effected by a diffusional mechanism (Figure 2), where the electron relay is either oxidized or reduced at the electrode surface. Diffusional penetration of the oxidized or

Figure 2. The electrical ‘wiring’ of a redox enzyme via a diffusional mobile electron-transfer mediator shuttling between an enzyme reaction center and an electrode.

Table 1. Diffusional electron transfer mediators applied to the immobilized enzymes.

Enzyme	Mediator	Mediator redox potential/mV (vs. SCE)	Ref.
Glucose oxidase, EC 1.1.3.4, from <i>Aspergillus niger</i>	1,4-Benzoquinone	39	57
	1,1'-Dimethylferrocene	100	58
	Ferrocenecarboxylic acid	275	59
	Phenazine methosulfate	-161	60
	Tetrathiofulvalene	300	61
	Tetracyanoquinodimethane	127	62
Xanthine oxidase, EC 1.2.3.3, from buttermilk	[Fe(CN) ₆] ⁴⁻	180	63
Cholesterol oxidase, EC 1.1.3.6, from <i>Pseudomonas</i> sp.	Ferrocenecarboxylic acid	275	64
Hydrogenase (Fe/S type)	Dimethylviologen	-681	65
Peroxidase, EC 1.11.1.7, from horseradish	[Fe(CN) ₆] ⁴⁻	180	66
Lactate dehydrogenase, EC 1.1.2.3 (Cyt. b ₂), from yeast	[Fe(CN) ₆] ⁴⁻	180	57a
Glucose dehydrogenase, EC 1.1.99.17, from <i>A.</i> <i>calcoaceticus</i>	1,1'-Dimethylferrocene	100	67
	Phenazine ethosulfate	-172	68
NADH dehydrogenase, EC 1.6.99, from <i>Bacillus</i> <i>stearothermophilus</i>	Ferrocenylmethanol	185	69
	Ferrocenecarboxylic acid	275	69

reduced relay into the protein yields a sufficiently short electron-transfer distance for the electrical activation of the biocatalyst. Ferrocene derivatives, ferricyanide, quinones, *N,N'*-dialkyl-4,4'-bipyridinium and other electroactive substrates have been employed for MET and the electrical activation of redox enzymes [53]. Diffusional MET can be applied to many biocatalytic systems lacking direct electrical contact with the conductive support, such as enzyme monolayers and multilayers [53] (including multilayer arrays composed of different enzymes [54]). Table 1 gives examples of immobilized enzymes that have been electrically contacted by the use of diffusional electron-transfer mediators. To improve the contact between electron relay molecules and redox enzymes, micellar systems composed of ferrocene-functionalized surfactants have been applied [55, 56]. Glucose oxidase has been electrically contacted using such redox-active micelles and an advantage in the electron-transfer efficiency over homogeneous electron relays was demonstrated.

Monolayers and multilayers of redox enzymes (e.g., glucose oxidase [70], bilirubin oxidase [71]) have been organized on electrode surfaces using bifunctional reagents (producing covalent bonding between the layers) [70, 71] or using bioaffinity

interactions (e.g., biotin–avidin [72] or antigen–antibody [73]). Multilayer arrays consisting of different enzymes (e.g., acetylcholine esterase and choline oxidase [54]) have been organized on electrode surfaces to provide cascades of enzymatic reactions. All these multilayer enzyme arrays were electrically contacted using diffusional mediators (e.g., ferrocenecarboxylic acid). The application of a rough electrode surface (an Au electrode with a roughness factor of ca. 15–30 [74]) allows an increase in the quantity of enzyme immobilized in mono- or multi-layer arrays, giving an improved amperometric response over architectures constructed on smooth electrodes [54].

Enantioselective MET has been addressed in a series of studies using diffusional chiral electron mediators [75–77]. The chiral electron relays (*S*)- and (*R*)-*N,N*-dimethyl-1-ferrocenylethylamine were reported to stimulate enantioselective bioelectrocatalyzed oxidation of glucose in the presence of glucose oxidase [75]. The bioelectrocatalyzed oxidation of glucose was enhanced ca. 2-fold in the presence of the (*S*)-isomer compared with the (*R*)-isomer. Kinetic analysis of the bioelectrocatalyzed oxidation of glucose by the two enantiomeric electron relays suggests that the protein induces chiral discrimination because of diastereoisomeric interactions during the mediator's penetration and dissociation pathways. Chiral discrimination in mediated electron transfer and subsequent bioelectrocatalyzed transformations has been observed using various diffusional electron relays and enzymes [76].

4.2.3 Electrochemistry of Enzymes at Electrodes Functionalized with Monolayers of Redox Relays

The electrochemical contacting of solution-state enzymes with surface-immobilized redox mediators is of interest in the study of the interfacial association of the enzyme with the mediators. The electrochemical kinetics of electrodes functionalized with layers of various mediators (e.g., viologens [78], C₆₀ derivative [79]) have been studied upon their interaction with diffusionally free enzymes. The temporary association of enzyme molecules to the relay-functionalized electrode surface has been demonstrated in these systems. This complexation results in enantioselective electrical contacting of redox enzymes when chiral electron mediator monolayers are used [80]. (*R*)- or (*S*)-2-methylferrocenecarboxylic acid (**2** or **3**) was assembled as a monolayer on an Au electrode (Figure 3A). The monolayer-mediated chiroselective oxidation of glucose in the presence of glucose oxidase and a ca. 1.9-fold enhanced biocatalytic oxidation of glucose was observed in the presence of the (*S*)-relay (**3**) enantiomer functionalized monolayer electrode (Figure 3B).

Microperoxidase-11 monolayers mediate electron transfer to hemoproteins [e.g., Cyt *c*, myoglobin (Mb) and hemoglobin (Hb)] by the formation of affinity complexes at the interface [81]. Microgravimetric analysis of these assemblies has determined the association constant of myoglobin to the MP-11 monolayer to be $K_a = 3.9 \times 10^2 \text{ M}^{-1}$. The MP-11–hemoprotein affinity complexes permit the mediated reduction of protein heme sites. Figure 4 shows the electrocatalytic cathodic currents originating from the MP-11 MET to the heme centers of Cyt *c*, Mb and Hb. The heme-containing monolayer can also stimulate MET to cytochrome-

dependent enzymes. The MP-11 monolayer was found to yield an affinity complex with the native cytochrome *b*₅-dependent nitrate reductase (NR, EC 1.9.6.1 from *Escherichia coli*), giving an NR surface coverage estimated as $3.8 \times 10^{-12} \text{ mol cm}^{-2}$ [82]. The association constant of the MP-11–nitrate reductase complex was determined by quartz crystal microbalance (QCM) measurements to be $K_a = 3.7 \times 10^3 \text{ M}^{-1}$. Electrocatalytic reduction of nitrate ions was achieved when the dissolved nitrate reductase was electrically contacted via the monolayer-immobilized MP-11.

4.2.4 Electrochemical Activation of Enzymes by the Attachment of Redox Relays to the Protein Backbone

The chemical modification of redox enzymes with electron relay groups permits the mediated electron transfer and the electrical ‘wiring’ of the proteins [83–85] (Figure 5A). The covalent attachment of electron-relay units at the protein periphery, as well as inner sites, yields short inter-relay electron-transfer distances. Electron ‘hopping’ or tunneling between the periphery and the active site allows electrical communication between the redox enzyme and its environment. The simplest systems of this kind involve electron relay-functionalized enzymes diffusively communicating with electrodes [83], but more complex assemblies including immobilized enzymes have also been reported.

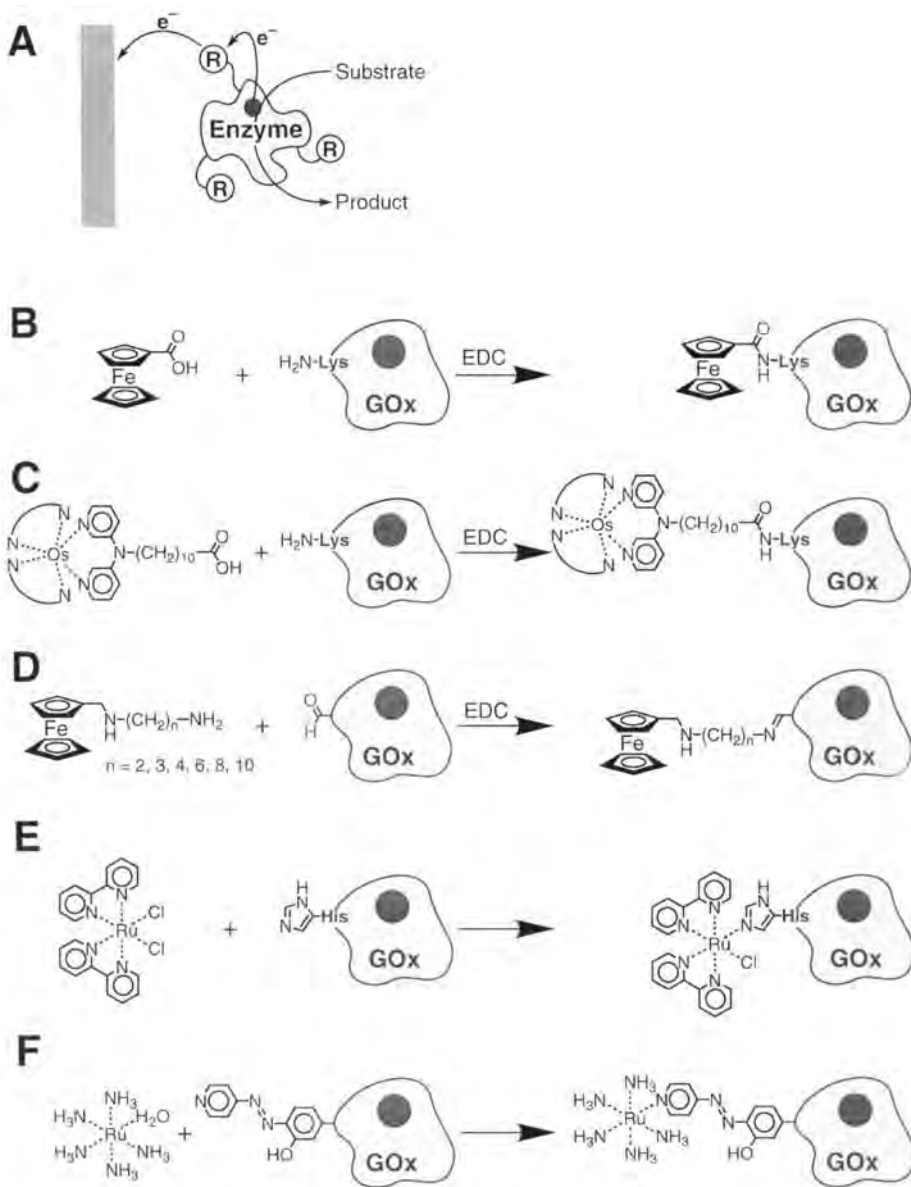

Figure 5. (A) A soluble enzyme electrically contacted with an electrode surface via redox-mediator groups covalently tethered to the protein backbone. (B)–(F) Different kinds of redox mediators tethered in various manners to the protein backbone. (B) A ferrocene unit linked to a lysine amino group via an amide bond generated in the presence of EDC. Diffusional electrochemistry of enzymes functionalized with tethered redox relays

Glucose oxidase can be covalently modified with ferrocene electron-relay groups by the carbodiimide coupling of ferrocenecarboxylic acid [83] (Figure 5B) or osmium(bis-4,4'-diaminobutane-*N,N*-bis-2-pyridyl-11-aminoundecanoic acid) [55] (Figure 5C) to the amino functions of the protein backbone. Other chemical procedures have also been used to produce relay groups peripherally bound to proteins. For example, carbonyl groups generated in glycoproteins (e.g., glucose oxidase) by oxidative treatment with periodate have been coupled to an amino-functionalized ferrocene via Schiff bases (Figure 5D) [84]. In another approach, ruthenium complexes have been attached to glucose oxidase using either natural histidine residues [86] (Figure 5E) or artificially introduced pyridine groups [83b] (Figure 5F) in the protein backbone. The randomly distributed relay groups provide electrical contact between the enzyme redox center and the unmodified electrode surface. The resulting amperometric response was measured by cyclic voltammetry (Figure 6A) and a calibration curve was derived (Figure 6B). It has been demonstrated that longer spacer groups bridging the electron relay groups and the enzyme provide higher mobility, shorten the electron-transfer distance, and thus enhance the enzyme's bioelectrocatalytic activity (Figure 7) [84]. Partial and reversible unfolding of the enzyme (using urea) during the covalent modification of the protein with the relay is also important since it allows the attachment of the electron mediator to inter-protein positions close to the active site of the enzyme [87].

While an increased loading of an electron mediator on a protein enhances the effectiveness of electrical contacting, the enzyme activity suffers owing to changes in its structure. The chemical modification of redox proteins with synthetic

Figure 7. Cyclic voltammograms of a bare Au electrode in the presence of glucose oxidase with ferrocene units covalently tethered to lysine residues (cf. Figure 5D) (2 mg mL^{-1}); in the absence of glucose (a) and in the presence of glucose, 40 mM for spacers with $n = 2$ (b), $n = 3$ (c) and $n = 8$ (d). electron mediators is always accompanied by this partial denaturing of the native biocatalyst, so the modification must be carefully controlled to achieve the optimum effect. With glucose oxidase modified by ferrocene units, the optimal mediated electron transfer was found at a loading corresponding to 12–13 electron relay units [87]. The rate constant of electron transfer between the enzyme's FAD site and the nearest electron relay group was found to be ca. 0.9 s^{-1} (substantially lower than electron transfer to the native dioxygen electron acceptor of the enzyme proceeding with a rate constant of ca. $5 \times 10^3 \text{ s}^{-1}$) [87]. Improvements in the efficiency of electrical contact may be possible by the use of protein engineering, genetic manipulation, or relay units placed at optimal positions in the enzyme structure.

Layered assemblies of enzymes functionalized with tethered redox relays

The immobilization of electron relay-functionalized enzymes on electrode supports allows the construction of integrated bioelectronic assemblies. Enzyme monolayers can be electrically contacted using electron relay units tethered to the protein [88, 89]. A glutathione reductase monolayer assembled on Au electrodes via a thiolate bridging unit (Figure 8A) was functionalized with *N*-methyl-*N'*-carboxyalkyl-4,4'-bipyridinium salts (**4**), where the chain length tethering the electron relay was systematically lengthened [88]. Electroreduction of the bipyridinium unit was found to activate the enzyme for the reduction of oxidized glutathione (GSSG). The effectiveness of GSSG reduction was controlled by the chain length tethering the electron relay to the protein, and longer bridging chains enhanced the electrobiocatalyzed reduction (Figure 8B). This phenomenon was rationalized in terms of shorter electron-transfer distances between the electron-relay sites and the enzyme redox center for the systems with long-chain tethered bipyridinium units. It was also found that in order to attain electron-transfer communication between the enzyme redox center and the electrode, it is important to modify the protein with the bipyridinium components in the presence of urea. Added urea partially unfolds the protein and permits the functionalization of inner lysine residues. These inner elec-

tron relay units provide a route for electron 'hopping' between the electrode and the active redox center of the protein, and thus contribute to the electrical contacting of the enzyme layer with the electrode [88].

Non-organized multilayers of electron relay-tethered enzymes have been constructed both by cross-linking on an electrode surface [90] and by incorporation into a conductive polymer on electrode supports [5]. A thin-film glucose oxidase layer, electrically contacted by ferrocene units, was assembled on an Au electrode by the cross-linking of GOx, 2-aminoferrocene and a monolayer of *p*-mercaptoaniline with glutaric dialdehyde [90] (Figure 9A). The immobilized enzyme was electrically contacted via the electron relay groups, providing electron propagation throughout the assembly. A calibration curve for the modified electrode in the presence of glucose was derived by cyclic voltammetry (Figure 9B). More controlled superstructures can be constructed in a stepwise manner by the layer-by-layer deposition of enzymes and the covalent attachment of relay units to the enzyme backbone. A multilayer of glucose oxidase (GOx) (Figure 10A) was modified with *N*-aminomethylferrocenecaproic acid (**5**) [70]. The ferrocene relay units are oxidized by the electrode, and they in turn oxidize the enzyme redox sites. The amperometric responses of the layered electrodes were found to be controlled by the number of protein layers, implying that all of the enzyme layers are electrically contacted with the electrode by the ferrocene units. The rate-limiting process in the oxidation of glucose is the electron transfer between the substrate and the enzyme redox center. This results in different amperometric responses of the electrode at different glucose concentrations, and allows the application of the layered enzyme electrode as a glucose biosensor (Figure 10B, inset). This approach allows control of the enzyme array's sensitivity by the number of enzyme layers in the assembly (Figure 10B). Different enzymes can also be introduced into the structure in different layers, allowing the construction of thin films that facilitate cascades of the biocatalytic transformations.

4.2.5 Electrical 'Wiring' of Enzymes Entrapped in Polymeric Matrices on Electrode Supports

Many examples of polymer-embedded enzyme bioelectrocatalytic electrodes exist [91–93]. The electrical contacting of enzymes immobilized in polymer matrices is achieved either by virtue of a conducting polymer, or by incorporating electron relay groups within the polymer, providing electron hopping between the enzyme and the electrode support.

Enzyme entrapment in conductive polymers

The formation of conductive conjugated polymers [e.g., polyacetylene, polypyrrole, polythiophene, polyaniline and poly(*p*-phenylene)] [92, 94] on electrodes by electropolymerization has been studied thoroughly [95]. If the electropolymerization is performed in a solution containing both the monomer and enzyme, then enzymes present in the immediate vicinity of the electrode surface become trapped in the

growing polymer. This kind of enzyme entrapment is desirable as it occurs without chemical reactions that could affect their activity. Electropolymerized films can be prepared easily in a rapid one-step procedure, and exact control of the layer thickness is possible based on the measurements of the electrical charge passed during the process. The method allows the precise electrogeneration of polymer coatings over small electrode surfaces of complex geometry, and is applicable to a very wide range of redox enzymes (e.g., glucose oxidase [60, 96, 97], horseradish peroxidase [18, 20, 98]). If the polymer is growing upon cyclic potential changes, charged reduced and oxidized states of the polymer are generated accordingly. This methodology has been used to assist the entrapment of charged enzyme molecules in the polymeric films. For example, negatively and positively charged enzymes have been incorporated into polyaniline films during the oxidation and reduction process, respectively [99].

Enzyme entrapment in conventional electrogenerated polymers such as polypyrrole, polyaniline or polyphenol occurs only due to presence of the enzyme molecules in the vicinity of the growing films [97, 100]. The ratio between biomolecules and the conductive polymer units is different from the ratio between the enzyme and monomer molecules in the original solution as it depends on the entrapment efficiency. An approach that allows control of this ratio is based on the application of amphiphilic monomers [101]. The procedure includes the solubilization of enzyme molecules (e.g., flavin reductase, horseradish peroxidase, galactose oxidase, choline oxidase, polyphenol oxidase, glucose oxidase, nitrate reductase, xanthine oxidase [92]) in an aqueous dispersion of amphiphilic pyrrole (e.g., derivatives **6–8**, Figure 11). Subsequently, the aqueous mixture is spread and dried on an electrode surface. The electropolymerization of the adsorbed mixture in an aqueous electrolyte provides the irreversible entrapment of a controlled amount of enzyme in the resulting polypyrrolic matrix. In contrast to simple monomers such as pyrrole, these amphiphilic monomers (e.g., **6**) possess a net positive charge, which promotes their association with anionic polar side-chains of enzyme molecules. This method also allows the tailoring of the local microenvironment for the enzyme molecules, e.g., highly hydrophobic or hydrophilic environments can be organized by the use of amphiphilic monomers **7** and **8**, respectively. The conductivity of the polypyrrole matrix allows the deposition and anodic polymerization of an additional amphiphilic monomer–enzyme mixture providing multienzyme structures with heterogeneous enzyme location [102]. For instance, the sequential deposition–electropolymerization of two different coatings has led to an amperometric flavin reductase/lactate dehydrogenase electrode for the interference-free determination of lactate.

Enzyme entrapment in polymers functionalized with redox relay units

Additional electron relay groups can be introduced into conductive polymer films to improve electrical ‘wiring’ of entrapped enzyme molecules [92]. The simplest approach involves the incorporation of ionic redox groups (e.g., ferrocyanide [103]) by employing the anion-exchange properties of the polymer. Consequently, co-entrapment of enzymes and anionic redox relays can be employed for electrical ‘wiring’ of the biocatalysts [97, 104]. The anion-exchange properties of regular

Figure 11. Structures of amphiphilic (6–8) and redox-functionalized (9–13) pyrrole derivatives applied for electropolymerization and entrapment of redox enzymes.

polypyrrole has been used to incorporate ferrocene carboxylate [59] and pyrrolo-quinoline quinone (PQQ) [105] for the electrical ‘wiring’ of glucose oxidase during the electrogeneration of a polypyrrole film. This simple approach to enhance the enzyme efficiency suffers from leakage of the noncovalently bound electron-transfer mediator from the polymeric matrix, however. Biocatalytic electrodes based on this technology therefore tend to be unstable and can not be utilized for *in vivo* measurements. To stabilize electron relays inside the polymeric matrix, new amphiphilic pyrrole derivatives (9–13) containing redox units have been synthesized (Figure 11) [92, 106], allowing the relay to be covalently incorporated into the polymer structure. A ferrocene-containing pyrrole derivative (12) and a flavin analog-functionalized pyrrole (13) have been employed to contact electrically glucose oxidase [92] and flavin reductase [107], respectively, realizing oxidative electron pathways for both

Figure 12. [106a] with permission.

enzymes. Enzymes operating in reductive pathways (e.g., nitrate reductase, pyridine nucleotide oxidoreductase) have been electrically contacted in polymeric matrices by the use of the viologen-functionalized pyrrole derivatives **9–11** [106a, 108]. Nitrate reductase electrically contacted by the viologen units of a polymer matrix was used for the amperometric detection of nitrate ions (Figure 12A), leading to the calibration curve given in Figure 12B.

A further approach to contact electrically polymer-bound enzymes involves the use of chemically synthesized polymers functionalized with redox units [109]. Polyelectrolytes represent the best choice for the optimization of interactions with enzymes and electrodes. Hydrophilic, charged, flexible chains of polyelectrolytes can easily surround protein molecules, and even penetrate inside them slightly, providing good contact between the protein structures and polymer backbone (Figure 13). Each unit of a polyelectrolyte is weakly adsorbed on an electrode surface, but because of the very large amount of the units in the polymer chain, the total binding is strong and some domains of the chain remain unattached, providing binding areas for protein molecules. Three-dimensional redox polyelectrolyte networks that electrically connect enzyme redox centers to electrodes have been formed in several systems [110, 111], of which enzyme ‘wiring’ hydrophilic epoxy cements are an excellent example [111]. In this case, the polymeric chain consists of a poly(vinylpyridine) backbone of which approximately one-sixth of the pyridines are complexed to $[\text{Os}(\text{bpy})_2\text{Cl}]^{+/2+}$ and about one-fifth of the pyridines have been reacted with 2-bromoethylamine to form pyridinium-*N*-ethylamine polycationic domains (**14**). This redox polyelectrolyte easily interacts with enzymes and ‘wires’ their redox centers by penetrating into the protein shell of, e.g., lactate oxidase, glycerol-3-phosphate oxidase and cellobiose oxidase [109a, 112]. Although negatively charged enzymes can strongly interact with this polycationic polymer even without cross-

Figure 13. A redox enzyme electrically 'wired' to an electrode surface by flexible polymer chains functionalized with redox-mediator groups and surrounding the enzyme at the electrode surface.

linking, cross-linking with the water-soluble diepoxide poly(ethylene glycol) diglycidyl ether (**15**) can further stabilize the system. For example, glucose oxidase was incorporated into a cross-linked polymeric matrix containing $\text{Os}(\text{bpy})_2$ units coordinated with the pyridine groups in the protein backbone. This enzyme-modified electrode shows an electrocatalytic anodic current in the presence of glucose (Figure 14A), leading to the calibration curve given in Figure 14A (inset). A similar polymer composed of a positively charged copolymer of allylamine and ferrocene-functionalized acrylic acid with the negatively charged proteins can be cross-linked with glutaric dialdehyde in the presence of GOx to yield the stable electrically 'wired' biocatalytic matrix [113]. This enzyme electrode also demonstrates the electrocatalytic current of glucose oxidation (Figure 14B). Successive additions of glucose at a fixed oxidative potential result in increases in the current (Figure 14B, inset). A neutral polyacrylamide chain carrying ferrocene units was used for entrapment of GOx molecules without assistance of electrostatic interaction [109b]. Many other polymers functionalized with different redox groups (e.g., quinones [114]) have also been employed for the electrical 'wiring' of entrapped redox enzymes. The free-radical polymerization of redox hydrogels (as an alternative to the electropolymerization process) has also permitted the efficient entrapment of enzymes [115].

4.2.6 Electrical 'Wiring' of Enzymes Incorporated into Inorganic Matrices

The incorporation of enzymes into inorganic composite matrices provides very stable biocatalyst interfaces that have important practical applications. Cheap and versatile matrices composed of different kinds of inorganic components (e.g. sol-gel

Figure 14. [116], graphite paste [117]), impregnated with electron-transfer mediators, cofactors, etc., have been investigated for biosensor design.

Electrical 'wiring' of enzymes incorporated into sol-gel matrices

Enzymes entrapped by sol-gel processing have received increased attention in recent years [116]. Sol-gel matrices offer several advantages for enzyme entrapment and the development of new biosensors including inherent low-temperature processing

conditions, tunable porosity, chemical inertness, and negligible swelling of the final glass matrix. To date, silicon alkoxide precursors have been most extensively studied because they are inexpensive and exhibit relatively slow overall reaction kinetics. Thus, one can readily prepare silica sol–gels that are doped with a wide variety of reagents (e.g., enzymes, electron-transfer mediators, cofactors, promoters, etc.) and tune the characteristics of the final matrix by adjusting the processing conditions (pH, precursor ratios, etc.). The versatility of these doped sol–gel matrices has been exploited in the construction of enzyme biosensors. Initially, optical detection was found to be more efficient than electrochemistry because of the very low conductivities of the silicate network [118], but efficient electron shuttles (conductive particles or mediators) were soon used to overcome this limitation, bringing about the start of an extraordinary growth in the development of new amperometric biosensors based on sol–gel-prepared silicates. These materials can be classified into two main categories: (i) silica sol–gel biosensors (consisting of molecular components immobilized in the matrix) and (ii) composite carbon–ceramic bioelectrodes (where the properties of the matrix are enhanced by the addition of carbon or other conductive materials).

The electrical ‘wiring’ of sol–gel–enzyme matrices can be achieved by either the application of solution-state electron relays that can penetrate through the matrix, or by the immobilization of redox mediators into the sol–gel. Horseradish peroxidase films deposited on carbon paste substrates and then covered with a thin silica sol–gel layer have been used to detect H_2O_2 in aqueous medium [119] or organic peroxides in nonaqueous solutions [120] in the presence of $[\text{Fe}(\text{CN})_6]^{4-}$ or ferrocene, respectively, acting as a mediator. The extension of this electrode configuration to other enzymes has led to the development of new amperometric sensors for glucose [121] and phenolic compounds [122]. Glucose oxidase has been electrically contacted in a sol–gel matrix using a ferrocene mediator incorporated into the matrix (Figure 15A) [123]. In this construction, more than 80 % of the GOx remained active in the sol–gel and the amperometric response agreed well with theoretical predictions. Construction of sol–gel–enzyme multilayer matrices allowed the amperometric sensing of glucose [124] and L-lactate [125] with linear responses within large concentration ranges.

The application of additional electroconductive materials such as carbon powder or metal particles in the preparation of bioceramic films can result in improved biosensors (Figure 15B). These electrodes benefit from both the porosity and rigidity of the silica matrix and from the electrical conductivity of the additive [116]. Composite sol–gel electrodes containing GOx and co-immobilized redox mediators have been applied to the preparation of glucose biosensors [126–129]. In these procedures, the redox mediator is either added as an isolated molecule during the gelification process (resulting in its physical entrapment in the silicate structure) [127] or is chemically bound to the silicate network [e.g., *N*-(3-trimethoxysilylpropyl)-ferrocenylacetamide (**16**) may be used as a functionalized co-monomer] [129]. The electron relay may also be incorporated by tethering to the protein backbone. Relay-functionalized GOx has been entrapped in composite graphite–sol–gel matrices [128, 130]. The presence of the relay facilitates electron hopping between the enzyme active site and nearest graphite particle, from where the electrons are trans-

Figure 15. Encapsulation of enzyme molecules into a sol-gel matrix containing redox-mediator groups (A) and with the addition of conductive graphite (or metal) particles (B).

ported to the electrode through the conductivity of the graphite component. Ferrocene-mediated electrical ‘wiring’ of GOx resulted in an amperometric response for the electrode in the presence of glucose [116a] (Figure 16). Metallic components for the improvement the matrix conductivity are often composed of a graphite core covered with a metallic (e.g., palladium, rhodium) shell [131]. More recently, the percolating carbon particles have been replaced by gold nanoparticles embedded together with the enzyme in the porous silicate matrix [132].

Electrical ‘wiring’ of enzymes incorporated into carbon paste composites

During the last decade there has been a virtual explosion of reports on the subject of amperometric biosensors based on carbon paste electrodes [117]. The concept of simply mixing an enzyme, an electron relay and a conductive powder into a paste is very attractive. Bulk modification of the entire electrode allows renewal of the electrode surface by polishing or cutting to expose a new and fully bioactive surface in the event of fouling or deactivation. This feature is certainly attractive compared with surface-modified electrodes, which have to be discarded or at least remodified after deactivation. The main challenge in the construction of carbon paste biosensors is the establishment of efficient electrical ‘wiring’. Electron-transfer mediators have been introduced into GOx pastes either as conjugates with the particles

Figure 16. The electrochemical response of a GOx-ferrocene-sol-gel-modified electrode in the presence of glucose: cyclic voltammogram before (a) and after (b) the addition of 10 mM glucose solution; phosphate buffer, pH 5.6; potential scan rate, 10 mV s^{-1} . Adapted from Ref. [116a] with permission.

or enzyme, or simply as free molecules. Examples of mediators include ferrocene derivatives [133] (monomeric or polymeric), benzoquinone and benzoquinone-functionalized polymers [134], viologen derivatives [135], tetrathiafulvalene (TTF) [136], tetracyanoquinodimethane (TCNQ) [18, 20, 137], TTF-TCNQ conducting salts [138], cobalt phthalocyanine [139], Meldola blue [140], methylene green [141] and cupric hexacyanoferrate [142], among others [117]. Many other redox enzymes have been incorporated into graphite paste electrodes with appropriate electron-transfer mediators and used as amperometric biosensors for their respective substrates [117b]. It should be noted that (a) low-potential redox relays (particularly viologens [135]) provide effective oxidation of the FADH_2 cofactor under potentials negative enough to prevent the non-specific oxidation of interferants, and (b) the application of NAD^+ -dependent enzymes (e.g. glucose dehydrogenase [143], alcohol dehydrogenase [144]) requires the incorporation of NAD^+ cofactor and a redox catalyst for the oxidation of NADH.

Multienzyme systems have been used in carbon paste electrodes, providing biocatalytic cascades that result in an analytical amperometric signal. For example, acetylcholine esterase (AChE) and choline oxidase (ChOx) have been co-immobilized in carbon pastes, either with monomeric TTF [145] or flexible ferrocene-containing polymers [146] as electron mediators. The primary reaction includes the hydrolysis of acetylcholine biocatalyzed by AChE, then the choline produced is oxidized by the electrically contacted ChOx giving an analytical amperometric signal corresponding to the acetylcholine concentration.

Although many biocatalytic systems have been immobilized in carbon paste electrodes successfully, the method is not general. Some enzymes, e.g., fructose dehydrogenase [15, 134a] and aldose dehydrogenase [147], have defied efforts at incorporation into the paste matrix without losing their activity. It is possible to introduce these enzymes to the surface of preformed carbon paste electrodes while retaining their biocatalytic potential, but this procedure does not exploit the many advantages of the carbon paste technique [117]. The construction and optimization

of the multicomponent matrices composed of graphite powder, organic oils, enzymes, redox mediators, cofactors, etc., is still a subject of intensive study.

4.2.7 Electrical ‘Wiring’ of Nano-engineered Enzymes

The site-specific modification of enzymes with a single electron-relay group located near to the redox cofactor and providing efficient electrical contact with the conductive support has been achieved by the reconstitution of enzymes with cofactors covalently linked to redox groups. Affinity interactions between enzymes and their cofactors at the electrode interface can allow the efficient electrical contacting of aligned proteins.

Enzymes reconstituted with semi-artificial cofactors linked to redox relays

A novel means for the establishment of electrical contact between the redox center of enzymes and their environment that is based on a reconstitution approach has recently been suggested [148, 149]. This concept involves the site-specific positioning of a single mediator group directly linked to the enzyme redox center as an electron shuttle between the biocatalyst and the electrode. According to this method (Figure 17A) the FAD redox centers of glucose oxidase or D-amino acid oxidase (AOx) were removed to yield the respective apo-enzymes. The amino-functionalized semi-synthetic cofactor *N*⁶-(2-aminoethyl)-FAD (**17**) was covalently linked to *N*-aminomethylferrocenecaproic acid (**5**) (Figure 18), then the bifunctional redox-active ferrocene–FAD cofactor was reconstituted into apo-GOx or apo-AOx. The resulting semisynthetic enzymes revealed bioelectrocatalytic features for the oxidation of glucose or D-alanine, respectively. Figure 17B shows cyclic voltammograms recorded in a solution of ferrocene–FAD-reconstituted GOx at a cystamine-modified electrode and in the absence and presence of glucose. The bioelectrocatalytic features of these enzymes (‘electroenzymes’) originate from the single ferrocene electron-relay group that electrically contacts the FAD center with the electrode surface. Tailoring of enzyme electrodes by the covalent attachment of redox-tethered enzymes or redox-reconstituted enzymes to a base monolayer interface is conceptually limited owing to the random anchoring of the electrocatalyst to the monolayer. Covalent linkage of the enzyme to the monolayer results in multiple orientations of the redox-active site relative to the electrode surface. Hence attachment of the electrically wired redox relay units to the protein yields a mixture of bioelectrocatalysts with different electrical communication features, and the performance of the enzyme electrode represents the average activity of these randomly oriented bioelectrocatalysts.

A major advance in the construction of electrically contacted enzyme electrodes involves the structural alignment of the enzyme redox center with respect to the electrode interface in conjunction with the site-specific positioning of a redox relay component between the enzyme redox center and the electrode. The design of such electrodes promotes a new level of molecular architecture of biomolecules on surfaces, enabling us to optimize the electrical contact of the resulting enzyme elec-

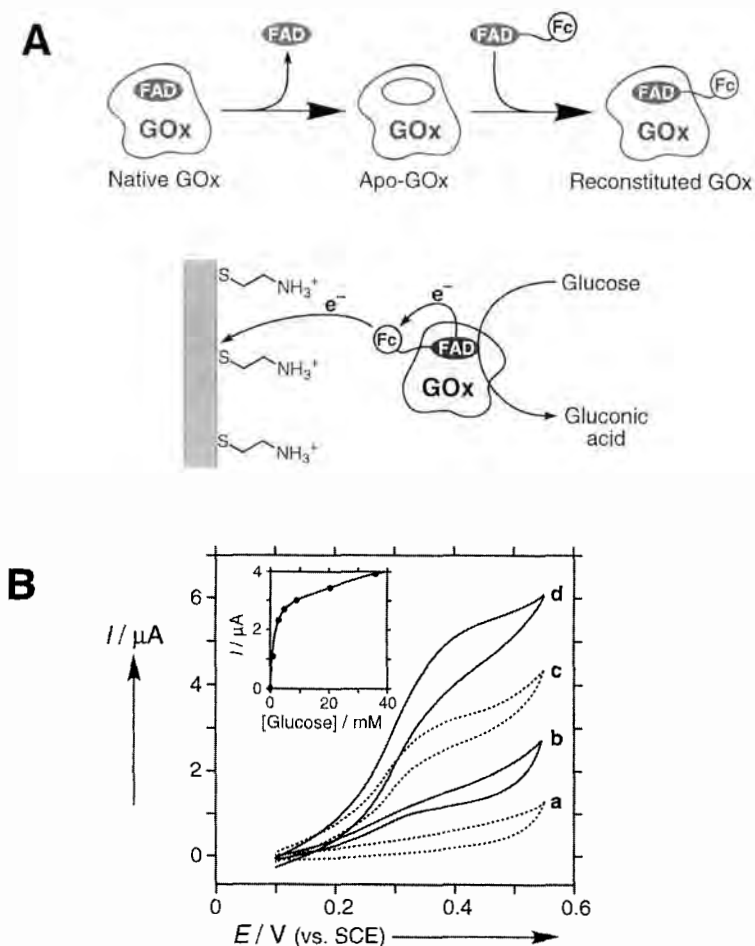

Figure 17. (A) The preparation of an electrically ‘wired’ enzyme by the reconstitution technique, involving the removal of the native FAD cofactor from the enzyme (e.g., GOx) and the incorporation of the artificial FAD–ferrocene dyad into the apo-enzyme. (B) Cyclic voltammograms of a system consisting of ferrocene–FAD–reconstituted GOx (1.75 mg mL^{-1}) at various concentrations of glucose: (a) 0, (b) 1, (c) 3 and (d) 20.5 mM. Experiments were performed in 0.1 M phosphate buffer, pH 7.3, at 35°C , using a cystamine-modified Au electrode, potential scan rate 2 mV s^{-1} , under argon. Inset: calibration curve of the biocatalytic current (0.5 V vs. SCE) at different glucose concentrations.

trode by the systematic alteration of the distances separating the electrode, catalyst and FAD components. The organization of an aligned reconstituted enzyme on a catalyst–FAD monolayer was recently realized by the reconstitution of an apo-enzyme on a surface functionalized with a relay–FAD monolayer [149, 150]. Figure 19A shows the method of assembly of the enzyme electrode. Pyrroloquinoline-quinone (**18**) was covalently linked to a base cystamine monolayer, and N^6 -(2-aminoethyl)-FAD (**17**) was then attached to the PQQ redox relay units. Following

Figure 18. Synthesis of a FAD–ferrocene dyad for the reconstitution of FAD-containing enzymes.

the construction of this organized electrode–PQQ–FAD assembly, apo-GOx was reconstituted on the semisynthetic FAD unit to yield an immobilized biocatalyst on the electrode with a surface coverage of 1.7×10^{-12} mol cm $^{-2}$. The resulting reconstituted enzyme reveals bioelectrocatalytic properties. Figure 19B shows cyclic voltammograms of the enzyme electrode in the absence and presence of glucose. When the substrate is present, an anodic electrocatalytic current is observed, implying electrical contact between the reconstituted enzyme and the electrode surface leading to the bioelectrocatalyzed oxidation of glucose. The PQQ site located at the protein periphery is constantly oxidized by the electrode, and PQQ-mediated oxidation of the FAD center activates the bioelectrocatalytic oxidation of glucose. The resulting electrical current is controlled by the recycling rate of the reduced FAD by the substrate and the concentration of glucose. Figure 19B (inset) shows the derived calibration curve for the amperometric responses of the reconstituted enzyme electrode at different concentrations of glucose. The resulting current densities are unprecedentedly high in the area of biosensors and bioelectronic devices (300 μ A cm $^{-2}$ at 80 mM of glucose). Control experiments revealed that reconstituted GOx on an electrode–FAD assembly (lacking the PQQ component) does not exhibit direct electron-transfer communication with the electrode surface, demonstrating that the PQQ relay unit is indeed a key component in mediating electron transfer between the biocatalyst and the electrode [149, 150].

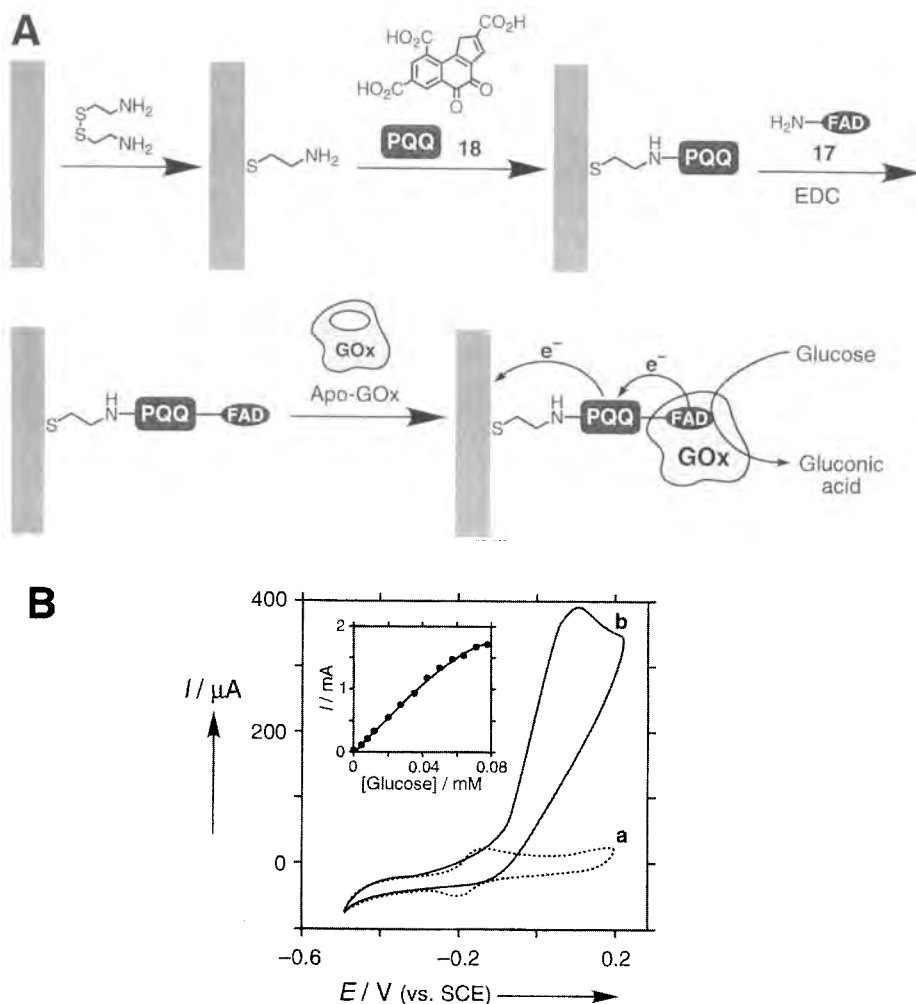

Figure 19. (A) The reconstitution of apo-glucose oxidase on a PQQ-FAD monolayer assembled on an Au electrode. (B) Cyclic voltammograms of the PQQ-FAD-reconstituted glucose oxidase on an Au electrode: (a) in the absence of glucose; (b) with glucose, 80 mM. Recorded in 0.1 M phosphate buffer, pH 7.0, under Ar, at 35 °C; potential scan rate, 5 mV s⁻¹. Inset: calibration curve corresponding to the amperometric responses (measured by chronoamperometry, $E = 0.2$ V vs. SCE) of the PQQ-FAD-reconstituted glucose oxidase enzyme electrode at different concentrations of glucose.

The electron-transfer turnover rate of GOx with molecular oxygen as the electron acceptor corresponds to ca. 600 s⁻¹ at 25 °C. Using an activation energy of 7.2 kcal mol⁻¹, the electron-transfer turnover rate of GOx at 35 °C is estimated to be ca. 900 s⁻¹ [149, 150]. A densely packed monolayer of GOx (ca. 1.7×10^{-12} mol cm⁻²) that exhibits the theoretical electron-transfer turnover rate is

expected to yield an amperometric response of ca. $300 \mu\text{A cm}^{-2}$. This figure indicates that reconstituted GOx on the PQQ–FAD monolayer exhibits an electron-transfer turnover of similar effectiveness to that observed with oxygen as mediator. In addition to the high sensitivity of the resulting enzyme electrode, the impressive efficiency of electrical contact has important consequences in the design of future enzyme electrodes. Amperometric glucose-sensing electrodes generally suffer from the non-specific oxidation of various interferants such as ascorbic acid or uric acid. Also, oxygen interferes with the current transduction as a result of nonelectrochemical oxidation of the enzyme redox site. The efficient electrical contact of the biocatalyst and the electrode, as well as the resulting effective electrobiocatalyzed oxidation of glucose suggest that the nonspecific oxidation of the interfering substrates and the reaction of the biocatalyst with oxygen should have little effect on the resulting current. Indeed, it was found that the transduced amperometric response at a glucose concentration of 5 mM was almost unaffected in the presence of oxygen or other interferents [149, 150]. The resulting selectivity of the reconstituted enzyme electrode and the high current densities achieved have further importance in the application of these electrodes as invasive glucose sensors. The pain accompanying the penetration of a needle electrode is proportional to its diameter, and microelectrodes are therefore being pursued for invasive sensing applications. The high electron-transfer turnover rate of the reconstituted biocatalyst in these systems suggests that even with the low surface area of the microelectrode, physically detectable current responses will be obtained.

The intermediate location of a redox relay between the electrode surface and the cofactor unit embedded into the enzyme is of key importance for the establishment of electrical contact between the enzyme and the electrode. For example, a pyrroloquinoline quinone monolayer assembled on an Au electrode was employed to reconstitute the PQQ-dependent apo-glucose dehydrogenase [151]. In this case the PQQ molecules play a role of the embedded cofactor and, since no additional electron relay was immobilized between PQQ cofactor and the electrode, the reconstituted enzyme was not electrically contacted with the electrode. The electrochemical oxidation of glucose by the reconstituted biocatalyst was only stimulated in the presence of a diffusional electron-transfer mediator. In other cases however, the orientation of the protein with respect to the electrode is sufficient to promote electron transfer without the need for a mediator. An Fe(III)–protoporphyrin IX complex was assembled as a monolayer on an Au electrode and apo-myoglobin was reconstituted with the heme–cofactor monolayer [152]. Although native myoglobin usually lacks direct electrical communication with electrode supports owing to insulation of the heme center, the surface-reconstituted myoglobin revealed electrical contact with the electrode. This property was attributed to the alignment of the heme center on the electrode surface in a structural orientation that facilitates electron transfer with the electrode.

Enzyme electrodes containing cross-linked cofactors, polypeptides or protein affinity complexes

Electrodes functionalized with monolayers of enzyme cofactors (e.g., NAD^+ monolayers) or redox proteins (e.g., heme proteins or heme polypeptides) demonstrate

the ability to form stable affinity complexes with the respective enzymes [153]. These interfacial complexes can be further cross-linked to produce integrated electro-biocatalytic matrices consisting of the biorelay units and the enzyme molecules. Electrically contacted biocatalytic electrodes of NAD^+ -dependent enzymes have been organized by the generation of affinity complexes between a catalyst- NAD^+ monolayer and the respective enzymes [154]. A PQQ monolayer covalently linked to an amino-functionalized nicotinamide adenine dinucleotide, N^6 -(2-aminoethyl)- NAD^+ (**19**), was assembled on an Au electrode. The resulting monolayer-functionalized electrode binds NAD^+ -dependent enzymes such as lactate dehydrogenase (LDH) and alcohol dehydrogenase (AlcDH) by affinity interactions between the cofactor and the biocatalyst (Figure 20A). These enzyme electrodes electrocatalyze the oxidation of the respective substrates, e.g., lactic acid or ethanol. The electro-biocatalytic transformations proceed via the biocatalyzed substrate-induced formation of NADH and its oxidation by the PQQ catalytic site. The resulting enzyme electrode reveals only temporary stability and ca. 25 % of the biocatalyst dissociates from the monolayer affinity complex to the electrolyte solution within 30 min. Cross-linking of the enzyme layer associated with the PQQ- NAD^+ cofactor monolayer with glutaric dialdehyde generates a stable, integrated, electrically contacted, cofactor-enzyme electrode (Figure 20A). The electrical response of a cross-linked layered PQQ- NAD^+ -LDH electrode in the absence (curve a) and presence (curve b) of lactate is given in Figure 20B, and a calibration curve for the amperometric responses of the integrated LDH layered electrode at different concentrations of lactate is shown in the Figure 20B (inset).

Protein-protein affinity interactions play a major role in biological electron transfer. For example, cytochrome *c* mediates electron transfer to different redox enzymes, e.g., cytochrome oxidase, lactate dehydrogenase, or copper enzymes [27, 38]. These mediated electron-transfer reactions proceed within interprotein affinity complexes [155]. Microperoxidase-11 (**1**) consists of the active-site microenvironment of cytochrome *c* [47], and is obtained by tryptic digestion of the native hemoprotein. Despite the structural similarities between MP-11 and cytochrome *c*, the heme sites of the oligopeptide and the native protein differ substantially in their redox-potentials ($E^\circ = -0.40$ V (vs. SCE) for MP-11 [50] and $E^\circ = +0.012$ V (vs. SCE) for cytochrome *c* [27, 38]). Microperoxidase-11 assembled [50, 82] as a monolayer on an Au electrode has been shown to stimulate electron transfer to hemoproteins such as myoglobin, hemoglobin and cytochrome *c* [81]. This mediated electron transfer is attributed to the formation of affinity complexes between the proteins and MP-11 at the electrode interface. The affinity interactions between MP-11 and hemoproteins or cytochrome-dependent enzymes have been used to assemble an electrically contacted nitrate reductase electrode [82]. The cytochrome-dependent nitrate reductase (NR) forms an affinity complex with the MP-11 monolayer associated with the electrode. Cross-linking of the enzyme-MP-11 affinity complex layer with glutaric dialdehyde generates a stable electrically contacted enzyme electrode that effects the bioelectrocatalyzed reduction of nitrate to nitrite (Figure 21A). The bioelectrocatalyzed transformation proceeds with a current efficiency of ca. 85 %, and the resulting enzyme electrode can be employed as an amperometric nitrate sensor (Figure 21B).

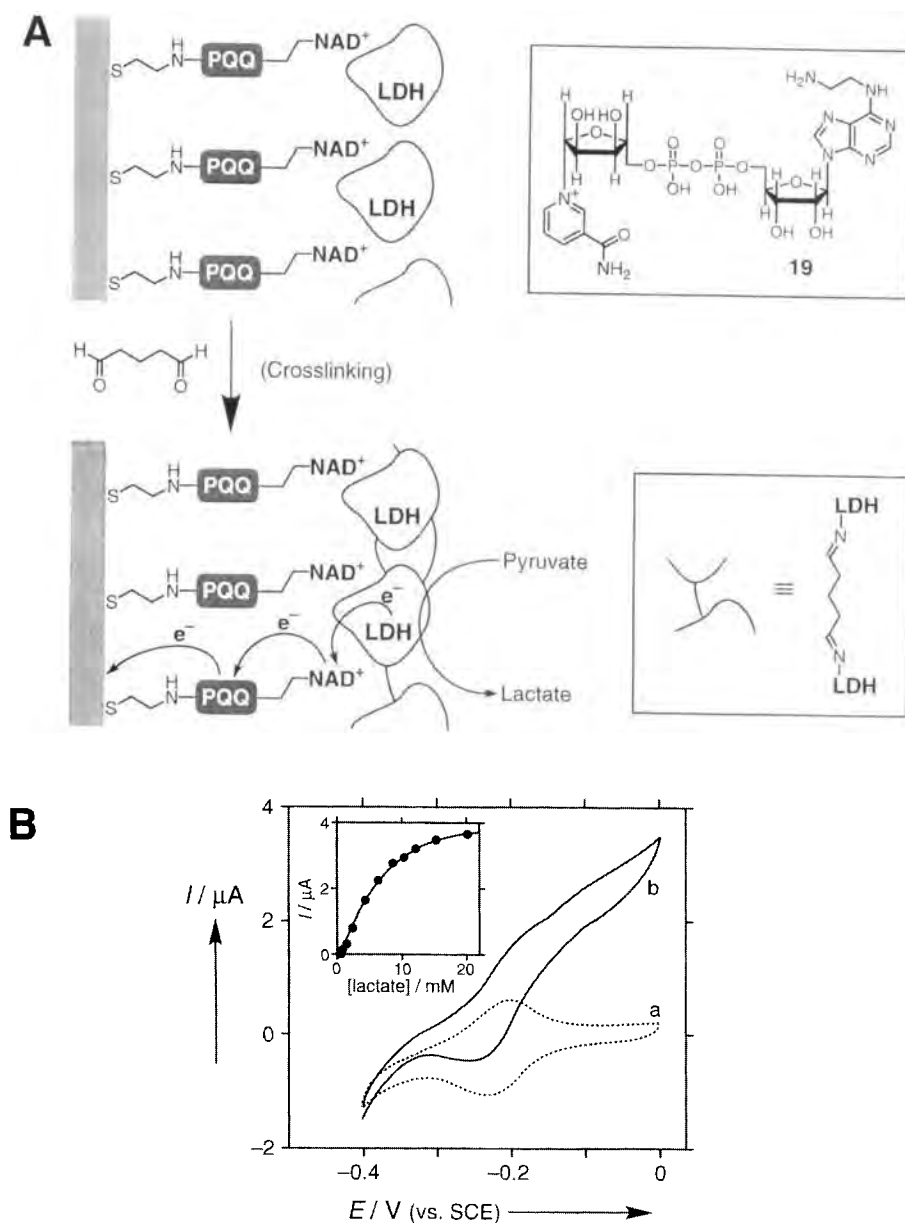

Figure 20. (A) The assembly of an integrated lactate dehydrogenase monolayer electrode by the cross-linking of an affinity complex formed between the enzyme and a PQQ–NAD⁺ monolayer-modified Au electrode. (B) Cyclic voltammograms of the integrated cross-linked PQQ–NAD⁺/lactate dehydrogenase electrode (roughness factor ca. 15): (a) in the absence of lactate; (b) with lactate, 20 mM. Recorded in 0.1 M Tris buffer, pH 8.0, in the presence of 10 mM CaCl₂, under Ar; potential scan rate, 2 mV s^{−1}. Inset: amperometric responses of the integrated electrode at different concentrations of lactate upon application of potential 0.1 V vs. SCE.

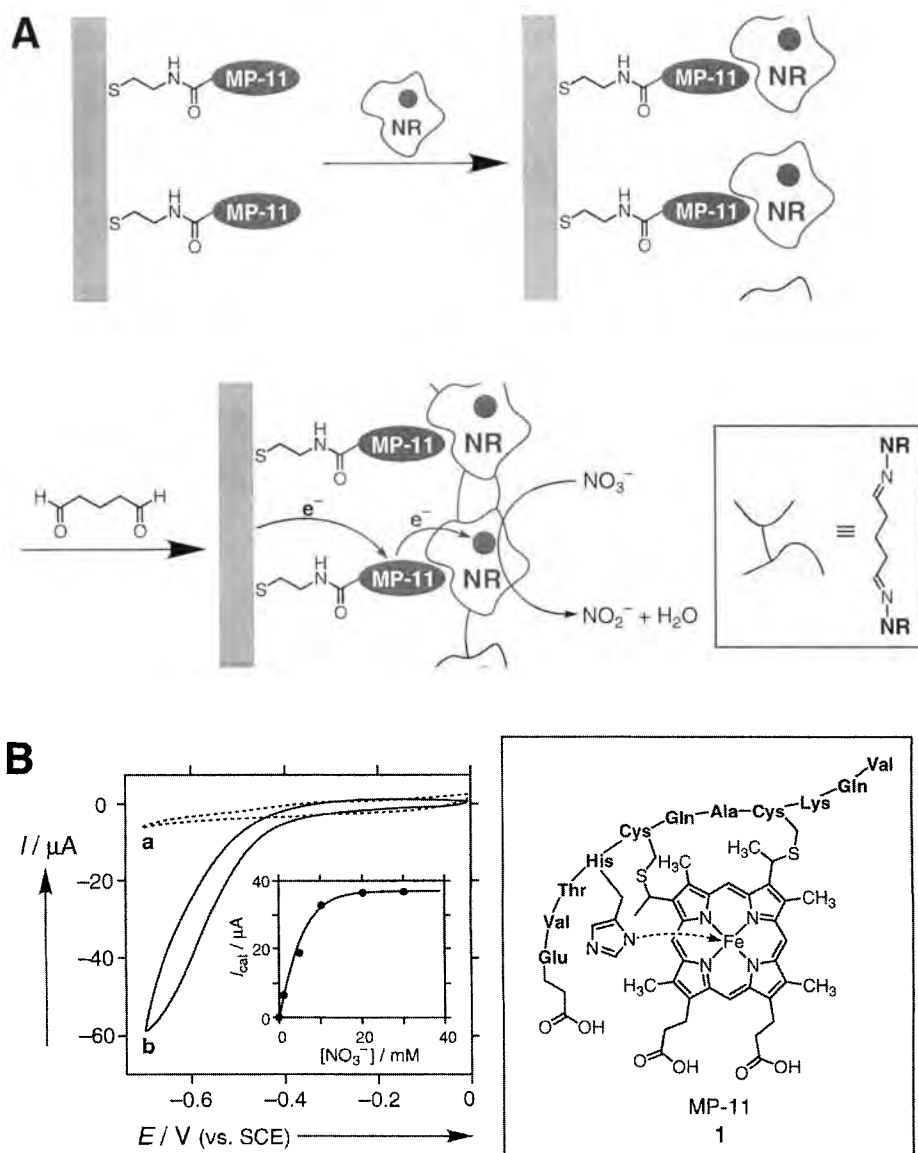

Figure 21. (A) The assembly of an integrated nitrate sensor electrode by the cross-linking of a microperoxidase-11-nitrate reductase (cytochrome-dependent, EC 1.9.6.1) affinity complex on an Au electrode. (B) Cyclic voltammograms of the integrated MP-11-NR monolayer-modified Au electrode (roughness factor ca. 15). (a) 0.1 M phosphate buffer, pH 7.0; (b) in the presence of KNO_3 , 20 mM. Potential scan rate, 5 mV s^{-1} . Inset: electrocatalytic cathodic currents ($E = -0.6 \text{ V}$ vs. SCE) transduced by the modified electrode at different concentrations of KNO_3 . Measurements were performed under argon.

Cobalt(II)–protoporphyrin IX-reconstituted myoglobin was also found to form an affinity complex with the MP-11 monolayer electrode [156]. The association constant of the affinity complex between the reconstituted myoglobin and MP-11 corresponds to $K_a = 1.6 \times 10^5 \text{ M}^{-1}$, and the electron-transfer rate constant in the resulting supramolecular complex is $k_{et} = 0.3 \text{ s}^{-1}$. The MP-11 mediates the electrocatalyzed reduction of Co(II)–myoglobin and the resulting cobalt hydride hydrogenates alkynes, e.g., acetylenedicarboxylic acid to maleic acid. Cross-linking of the Co(II)-reconstituted myoglobin affinity complex at the MP-11 monolayer with glutaric dialdehyde generates a stable electrode for the electrocatalytic hydrogenation of acetylenedicarboxylic acid with a current yield of ca. 80 %.

Recently, de novo-synthesized four-helix polypeptides were applied to mimic functions of cytochrome *b* and to tailor layered cross-linked electrocatalytic electrodes. A four-helix bundle de novo protein (14 728 Da) that includes four histidine units in the respective ‘A’-helices was assembled on Au electrodes (Figure 22A). Two units of Fe(III)–protoporphyrin IX were reconstituted into the assembly to yield a vectorial electron-transfer cascade [157]. The de novo-synthesized protein assembly forms affinity complexes with the cytochrome-dependent nitrate reductase (NR) and with Co(II)–protoporphyrin IX-reconstituted myoglobin [158]. The resulting layered complex of Fe(III)–de novo protein–NR or Fe(III)–de novo protein–Co(II)-reconstituted myoglobin was cross-linked with glutaric dialdehyde to yield electrically contacted electrocatalytic electrodes. The Fe(III)–de novo protein–NR electrode assembly was applied for the electrocatalyzed reduction NO_3^- to NO_2^- and acted as an amperometric NO_3^- sensor (Figure 22B). The Fe(III)–de novo protein–Co(II)-reconstituted myoglobin integrated electrode stimulated the electrocatalyzed hydrogenation of acetylenedicarboxylic acid to malic acid.

Artificial compounds capable of substituting natural materials and exhibiting affinity interactions with proteins have also been immobilized as monolayers on electrodes and used as ‘instruction matrices’ for assembling further protein layers. Artificial dyes exhibiting affinity interactions to NAD(P)⁺-dependent enzymes (e.g., Cibacron Blue F3G-A) have been assembled as monolayers on Au electrodes, which could then be used for the anchoring of NAD⁺-dependent enzymes such as lactate dehydrogenase [159]. The affinity complexes consisting of the layered dye–enzyme matrices exist in a bioactive configuration, but lack electrical contact with the electrode. Addition of the diffusional NAD⁺ cofactor was found to trigger biocatalytic activity from the enzyme electrodes.

4.2.8 Biosensor, Bioelectronic and Biotechnological Applications of Electrically ‘Wired’ Enzymes

Biosensors constructed from ‘wired’ enzyme assemblies

The electrochemical activation of enzyme electrodes results in the electrobiocatalyzed oxidation or reduction of a substrate specific to the biocatalyst. The rate of the biotransformation is dependent on the substrate concentration, hence these assemblies provide a basis for the construction of analytical biosensors [160]. The

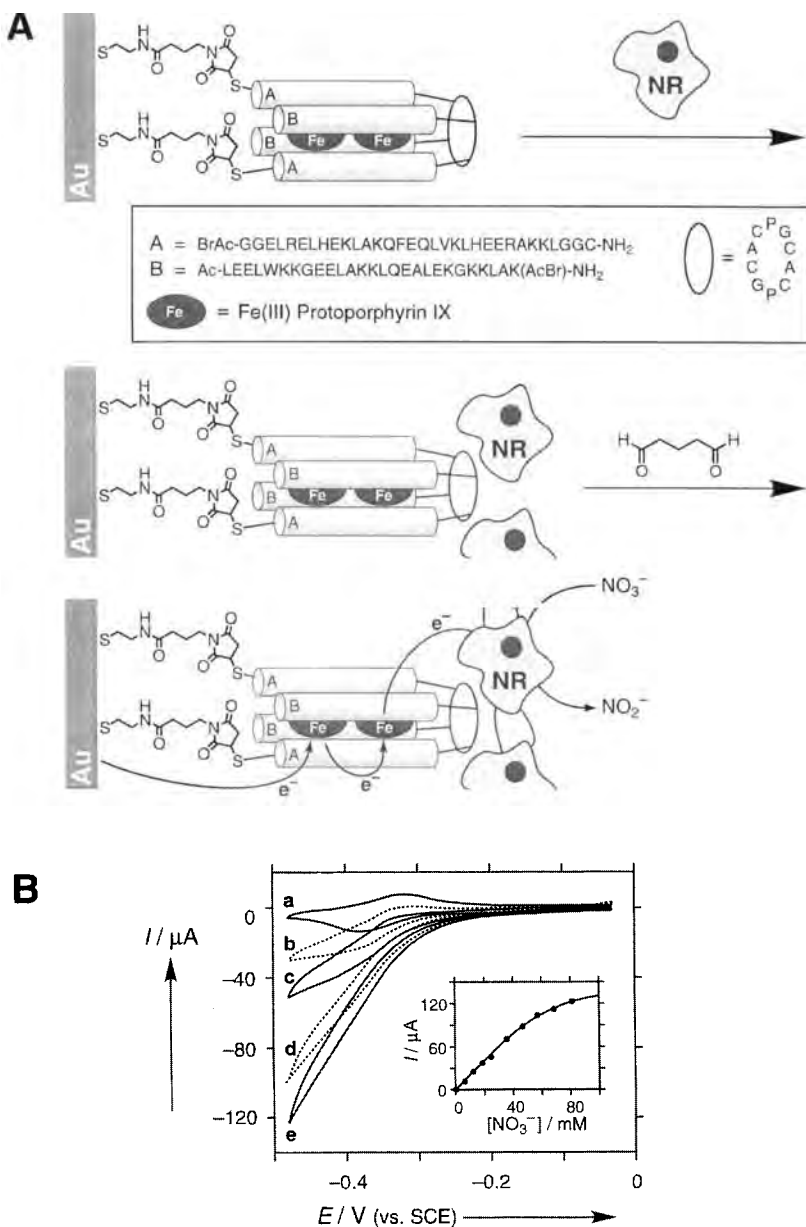

Figure 22. (A) The assembly of a nitrate-sensing electrode by the cross-linking of an affinity complex formed between nitrate reductase (cytochrome-dependent, EC 1.9.6.1), NR and an Fe(III)-protoporphyrin reconstituted de novo four-helix-bundle protein. (B) Cyclic voltammograms of the NR–two heme–reconstituted de novo protein-layered Au electrode at nitrate concentrations of (a) 0, (b) 12, (c) 24, (d) 46 and (e) 68 mM. Inset: calibration curve for the amperometric response of the electrode at different nitrate concentrations (at $E = -0.48 \text{ V vs. SCE}$). Potential scan rate, 5 mV s^{-1} ; 0.1 M phosphate buffer, pH 7.0, under argon; electrode roughness factor, ca. 20.

continuous monitoring of endogenous compounds or drugs by implantable biosensors permits the closer surveillance of patients via a rapid return of clinical information [161]. Such real-time measurements are thus highly desirable in intensive care units, during surgery or for the management of diabetes, as they offer an early warning of changes in a patient's condition, allowing rapid corrective action to be undertaken, possibly via an artificial biofeedback system. Much attention has been given to the probing of blood glucose levels as an aid to diabetes therapy [160]. Several other important metabolites can also be readily detected using amperometric biosensors based on electrically 'wired' enzymes (e.g., biosensors for lactate [162], bilirubin [71, 163], amino acids [164] and peptides [165] have been developed using lactate oxidase or lactate dehydrogenase, bilirubin oxidase, amino acid oxidase and tyrosinase, respectively). Amperometric biosensors for monitoring drugs have also received considerable attention (e.g., for assays of acetaminophen [166] and theophylline [167] using aryl acylamidase and theophylline oxidase, respectively). In addition to medical applications, electrically 'wired' redox enzymes have found many uses in food technology and biotechnology (e.g., for analysis of carbohydrates, organic acids, alcohols, additives, pesticides and fish/meat freshness [168]), in environmental monitoring (e.g., for analysis of pollutants and pesticides [169]) and in defense applications (e.g., for detection of toxins and pathogenic bacteria [170]).

Electrocatalyzed biosynthesis by 'wired' enzyme assemblies

Association between enzymatic and electrochemical reactions has provided efficient tools not only for analytical but also for synthetic purposes. In the latter field, the possibilities of enzymatic electrocatalysis, e.g., the coupling of glucose oxidation (catalyzed either by glucose oxidase or glucose dehydrogenase) to the electrochemical regeneration of a co-substrate (benzoquinone or NAD^+) have been demonstrated [171, 172]. An electroenzymatic reactor has also been developed [172] to demonstrate how the enzyme-electrode association can be used to produce biochemicals on a laboratory scale.

The electrochemical regeneration of cofactors required for the operation of redox enzymes is an important issue for the development of bioreactor technology. Most redox enzymes, dehydrogenases, require $\text{NAD(P)}^+/\text{NAD(P)H}$ coenzyme for their operation, hence the electrochemical regeneration of its oxidized or reduced form [NAD(P)^+ or NAD(P)H] is vitally important for the realization of biosynthetic reactions. Electrocatalytic oxidation of NAD(P)H using many different kinds of catalysts [173], such as *o*-quinones [174], *p*-quinones [175], phenazine, phenoxazine and phenothiazine derivatives [176], ferrocenes [177] and Os complexes [178], has been applied to the regeneration of NAD(P)^+ . Electrocatalytic or bioelectrocatalytic reduction of NAD(P)^+ using Rh complexes [179] or enzymes (e.g., diaphorase [180]) have been used to regenerate NAD(P)H . The regenerated NADH can be used to drive secondary enzymatic reactions with the participation of NADH-dependent enzymes, e.g. lactate dehydrogenase [179b, 180b]. NAD(P)^+ derivatives immobilized by covalent attachment to polymer matrices or protein backbones have been used in enzyme reactors [181]. Another important coenzyme Q, ubiqui-

uinone, playing an important role in metabolism, can be regenerated at an electrode [182] and applied to drive secondary enzymatic reactions with the participation of membrane enzymes (e.g., fumarate reductase), resulting in the production of biologically important compounds [183].

Low-potential electron-transfer mediators such as viologens can substitute natural cofactors (particularly NADH) in some enzymatic reactions [184]. The electrochemical reduction of viologens has been studied extensively [185] and they and other reductive electron mediators have been utilized to drive enzyme-catalyzed reactions [186]. For instance, the electrochemical reduction of NAD(P)^+ to NAD(P)H with a current efficiency of more than 97 % was achieved using alcohol dehydrogenase in the presence of acetophenone as an electron mediator [187]. The addition of acetone or acetaldehyde as a substrate to the above bioelectrocatalytic system allowed the reduction of the substrate to the corresponding alcohol at alcohol dehydrogenase accompanied by the oxidation of the resulting NAD(P)H .

Biocatalytic synthetic reactions also include carbon dioxide fixation with the production of methanol in artificial multi-enzyme systems [188]. Formate dehydrogenase (FDH, EC 1.2.1.2) can catalyze the reduction of carbon dioxide to formate, and methanol dehydrogenase (MDH, EC 1.1.99.8) can catalyze the reduction of formate to methanol. Both of these enzymes require NAD^+/NADH cofactor, and in the presence of the reduced dimethyl viologen mediator (MV^{+}), they can drive a sequence of enzymatic reactions. The cascade of biocatalytic reactions results in the reduction of CO_2 to formate catalyzed by FDH followed by the reduction of formate to methanol catalyzed by MDH. A more complex system composed of immobilized cells of *Parococcus denitrificans* has been demonstrated for the reduction of nitrate and nitrite [189].

Biofuel cells based on ‘wired’ enzyme assemblies

One of the more attractive applications of bioelectrocatalytic electrodes is the development of biofuel elements. The biofuel cell utilizes biocatalysts for the conversion of chemical energy to electrical energy [190]. Abundant raw materials (e.g., methanol, glucose) can be used as fuel substrates for the oxidation, and molecular oxygen or H_2O_2 can act as the oxidizer. The fact that an electrically ‘wired’ enzyme can catalyze the oxidation (e.g., glucose, methanol, lactic acid) or reduction (e.g., H_2O_2) of substrates allows the use of enzyme-modified electrodes as key elements of biofuel cells. Accordingly, a biofuel cell element based on the bioelectrocatalytic oxidation of glucose by H_2O_2 was constructed [191] (Figure 23A). An electrically contacted glucose oxidase monolayer (assembled on an electrode by the reconstitution of apo-glucose oxidase on a PQQ–FAD layer; cf., Section 4.2.7 and Figure 19) was used as the anode, whereas a microperoxidase-11-functionalized electrode acted as the cathode in the system. The bioelectrocatalyzed oxidation of glucose proceeds at the anode, whereas the MP-11 catalyzed reduction of H_2O_2 occurs in the catholyte compartment. The current–voltage behavior of the biofuel cell at different external loads and at optimized concentrations of the oxidizer and fuel substrates are shown in Figure 23B. The maximum power extracted was 32 μW at an external load of 3 k Ω (Figure 23B, inset). The configuration of this biofuel cell

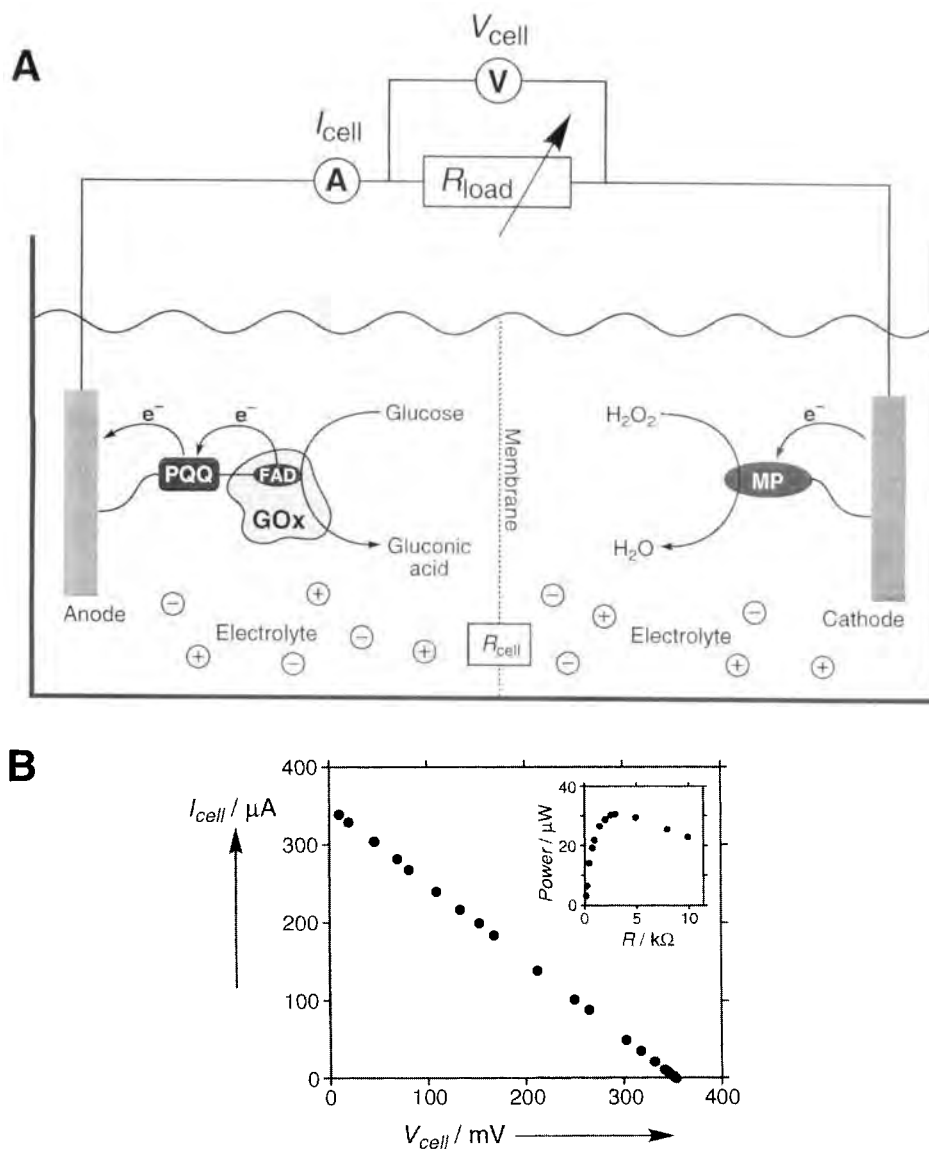

Figure 23. (A) Schematic configuration of a biofuel cell employing glucose and H_2O_2 as fuel and oxidizer, and using PQQ-FAD/reconstituted GOx and MP-11-functionalized electrodes as biocatalytic anode and cathode, respectively. (B) Current-voltage behavior of the biofuel cell at different external loads. Inset: electrical power extracted from the biofuel cell at different external loads.

represents a very general method for the development of future biofuel cell elements as it can be extended to other oxidative enzymes and fuel substrates such as methanol oxidase or lactate oxidase and the respective alcohol or lactic acid fuel substances.

The next generation of biofuel cells could utilize the anode described above (based on the reconstituted GOx) together with a cathode based on an aligned Cyt *c* (from *Saccharomyces cerevisiae*)–cytochrome oxidase couple providing the reduction of O₂ to water (Figure 24A). Since the reconstituted GOx provides extremely efficient biocatalyzed oxidation of glucose that is not affected by oxygen, the anode can operate in the presence of oxygen. Thus, this biofuel cell uses O₂ as an oxidizer and glucose as a fuel without the need for compartmentalization of the anode and cathode [192]. The cell operation was studied at different external loads (Figure 24B), and achieved a fill factor of ca. 40 % with a maximum power 4 μW at an external load of 0.9 kΩ.

Bioelectronic architectures based on ‘wired’ enzyme assemblies

Finally, electrochemically ‘wired’ enzymes and redox proteins can be applied as electronic elements in biomaterial-based electronic systems such as biomolecular switches, rectifies and amplifiers [193, 194]. One example utilized a four-helix bundle de novo protein reconstituted with two heme centers, each with a different potential. When the de novo protein was assembled as a monolayer such that the two redox centers were located at different distances from the electrode, the assembly was shown to display vectorial electron transfer, thus functioning as a biomolecular rectifier (Figure 25A) [158]. The Fe(III)–heme site close to the electrode support exhibits the more negative redox potential ($E^\circ = -0.43$ V vs. SCE). Electron transfer to this heme site is therefore accompanied by intramolecular electron transfer to the second heme center ($E^\circ = -0.36$ V vs. SCE) due to the potential gradient. Since the second process is fast, the electron-transfer rate of reduction is controlled by the primary electron-transfer rate to the heme site close to the electrode. The more negative potential of this site requires that each reduced heme must be oxidized directly, i.e., the oxidation of the reduced two-heme de novo protein cannot proceed by an intramolecular path, and the two reduced sites must be oxidized independently with different electron-transfer kinetics. A double-step chronoamperometric experiment was performed to demonstrate the rectifier function of this system (Figure 25B). The potential applied to the two-heme de novo protein assembly was stepped from -0.2 to -0.5 V (vs. SCE), and the step was interrupted after 70 ms. A reverse step from -0.5 to -0.2 V was then applied to oxidize the reduced assembly. The duration of the cathodic step (70 ms) was tuned to allow only a single electron transfer per protein assembly. As indicated previously, the heme center near the electrode surface is rapidly reduced, and mediates very fast electron transfer to the second site. Thus, upon the application of the cathodic step and the transfer of a single electron to the assembly, a fast cathodic current decay ($k_{\text{et}}' = 40$ s⁻¹) is observed, and the electron is ultimately positioned on the remote heme site. Upon application of the reverse potential step, the system exists in a configuration where the heme center close to the electrode is in the oxidized state,

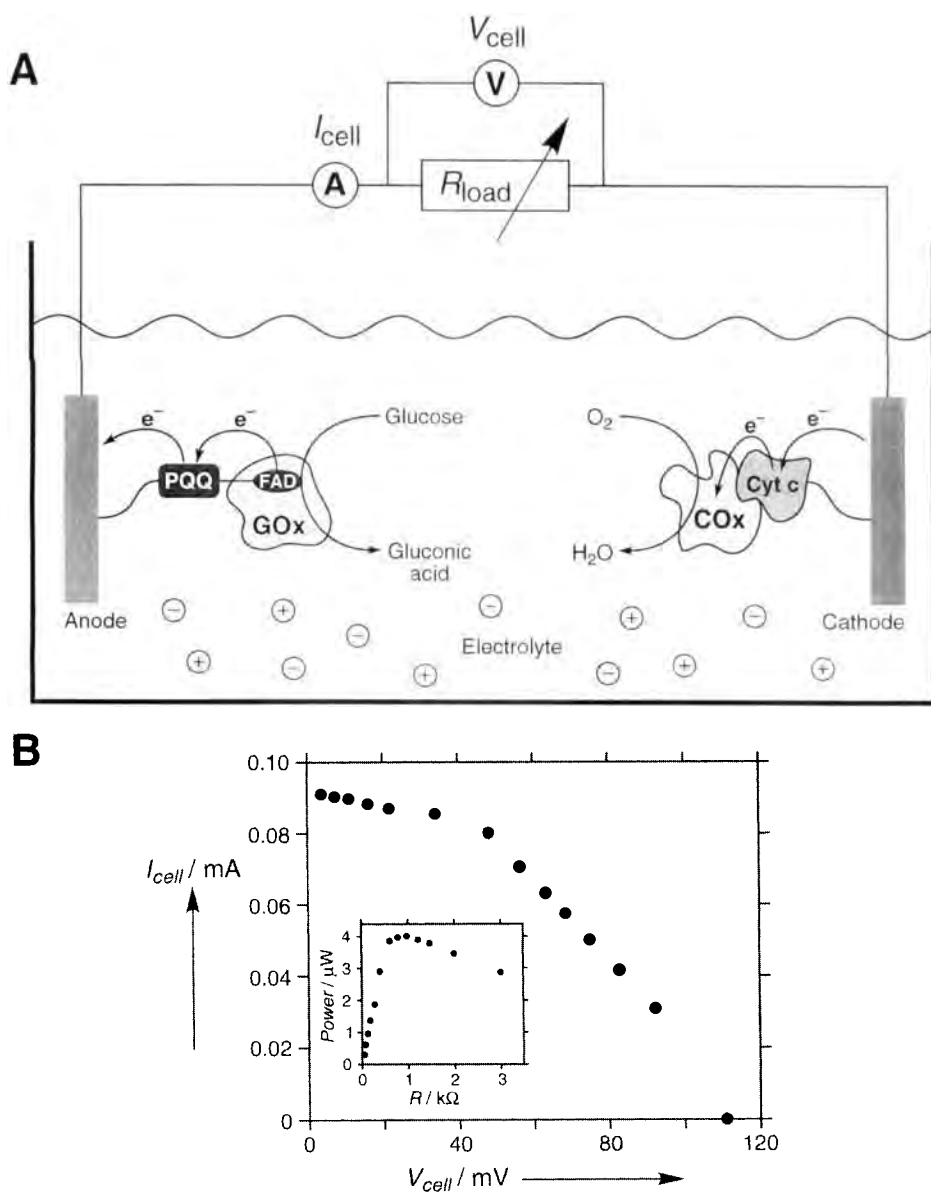

Figure 24. (A) Schematic configuration of a noncompartmentalized biofuel cell employing glucose and O_2 as fuel and oxidizer, and using PQQ–FAD/GOx- and Cyt *c*/COx-functionalized electrodes as biocatalytic anode and cathode, respectively. (B) Current–voltage behavior of the biofuel cell at different external loads. Inset: electrical power extracted from the biofuel cell at different external loads.

Figure 25. (A) Vectorial electron transfer in the two-heme-reconstituted de novo protein molecules organized as a monolayer at an electrode surface. (B) Transient current recorded with the two-heme reconstituted de novo protein monolayer during the double-potential step chronoamperometric experiment. The potential steps from -0.2 to -0.5 V (vs. SCE) to reduce the hemes in the protein, and after 70 ms the potential steps back, from -0.5 to -0.2 V, to oxidize the reduced hemes. The experiment was performed in 0.1 M phosphate buffer, pH 7.0, under argon.

whereas the remote heme site is reduced. Thus, only very slow oxidation of the remote heme site ($k_{\text{et}}'' = 1.0 \text{ s}^{-1}$) is observed. The system operates as a biomolecular rectifier, allowing fast electron transfer in one direction and only slow electron transfer in the other [158].

The photoswitchable electroactivation of biocatalytic processes can be achieved in systems where enzymes or redox proteins are electrically contacted using photoisomerizable ‘command’ interfaces or electron mediators [195–200]. For example, a mixed monolayer consisting of pyridine thiol and nitrospiropyran thiol (**20**) reveals properties of a light-controlled ‘command’ interface for the cytochrome *c* electrochemistry [195, 198]. On a gold surface, the pyridine thiol monolayer functions as a promoter for the Cyt *c* electrochemical reduction–oxidation process [27, 28]. The second monolayer component, nitrospiropyran thiol, is a photoisomerizable organic material that can be transformed by light ($360 \text{ nm} < \lambda < 400 \text{ nm}$) from the spiropyran state (**20a**) to the protonated merocyanine state (**20b**). The reverse photoisomerization from **20b** to **20a** proceeds upon illumination with visible light ($\lambda > 475 \text{ nm}$). The monolayer composed of the pyridine promoter groups and neutral molecules (**20a**) provides efficient reduction and oxidation of Cyt *c*, allowing enzymatic reactions that require the participation of a Cyt *c*-dependent enzyme. A biocatalytic cascade of reductive reactions was achieved in the presence of cytochrome oxidase (COx) and O_2 (Figure 26A). Oxidative reactions with the participation of lactate dehydrogenase resulted in the lactate oxidation (Figure 26B). When the photoisomerizable groups are transformed into the positively charged protonated merocyanine state (**20b**), the positively charged Cyt *c* molecules are repulsed from the electrode surface and are no longer electrically contacted (Figure 26C). In this case, not only is Cyt *c* electrochemistry inhibited, but so are any secondary reactions. Switching between the electrochemically contacted system and

Figure 27. mance of glucose oxidase [200, 201] and electrocatalytic regeneration of NAD⁺ cofactor [202].

Photoswitchable electrical communication between enzymes and electrodes has also been achieved by the application of photoisomerizable electron-transfer mediators [195, 199]. Diffusional electron mediators (viologen or ferrocene derivatives) were functionalized with photoisomerizable spiropyran/merocyanine units. These mediators can be reversibly photoisomerized from the spiropyran state to the merocyanine state ($360 < \lambda < 380$ nm) and back ($\lambda > 475$ nm). An enzyme multilayer array composed of glutathione reductase or glucose oxidase was electrically contacted only when the photoactive group linked to the redox relay (viologen or ferrocene derivative, respectively) was in the spiropyran state.

Similar photoisomerizable spiropyran/merocyanine (SP/MRH⁺) groups have been covalently tethered to the glucose oxidase backbone, resulting in control over the enzyme's activity [195, 197]. This control results from the influence of the isomeric state of the randomly tethered photoactive groups on the protein conformation. A more elegant approach involved the reconstitution of an apo-enzyme (e.g., apo-glucose oxidase) with the FAD cofactor covalently linked to a spiropyran/merocyanine photoisomerizable group [203] (Figure 28A). This single photoisomerizable group locates very near to the enzyme active site, providing a very strong effect on the enzyme activity. Cyclic voltammetry of a monolayer assembly consisting of reconstituted GOx in the presence of a diffusional electron relay revealed photoswitchable properties of the enzyme (Figure 28B).

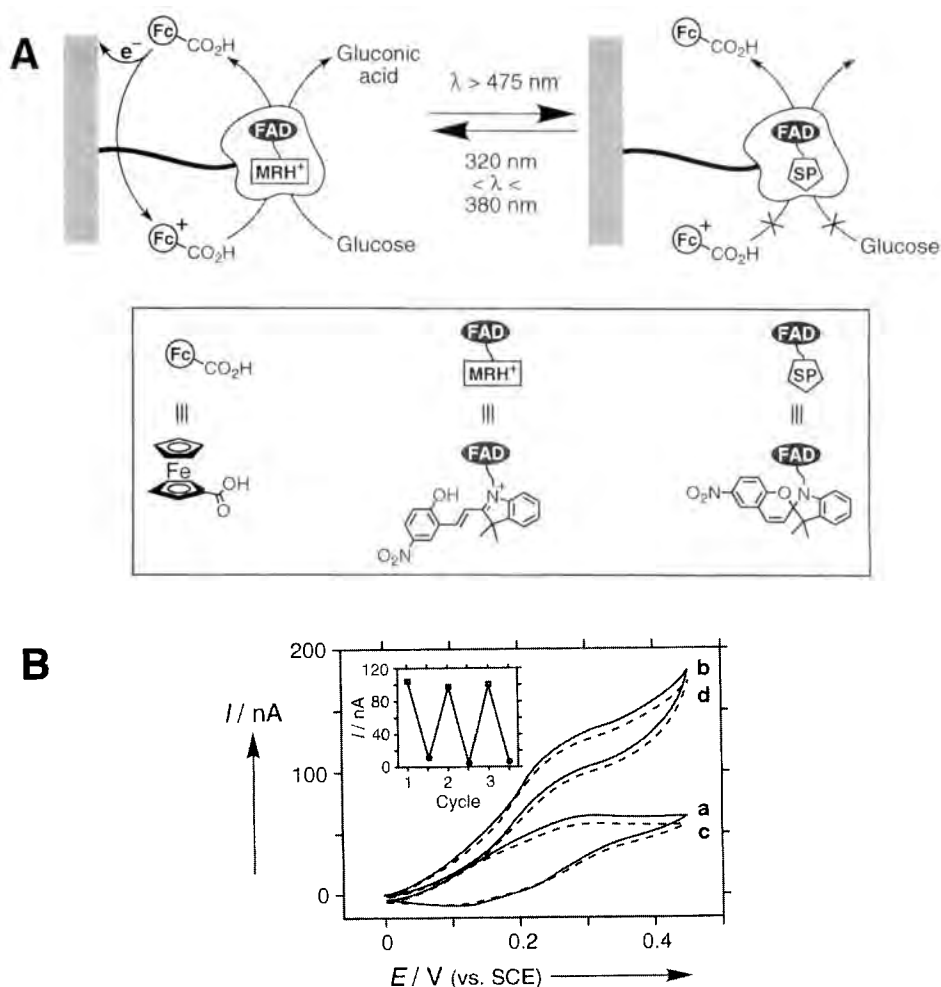

Figure 28. (A) The photoswitchable oxidation of glucose by immobilized GOx reconstituted with a spiropyran-modified FAD and with ferrocenecarboxylic acid as a diffusional electron mediator. (B) Cyclic voltammograms of the modified electrode in the presence of glucose (50 mM), Fc-CO₂H (50 μ M) and with the electrode (a, c) in the spiro (SP) state, and (b, d) in the merocyanine (MRH⁺) state. Recorded in 0.01 M phosphate buffer, pH 7.3; potential scan rate, 5 mV s⁻¹. Inset: switching behavior of the electrocatalytic current as a function of the state of the photoisomerizable group.

Command surfaces based on isomerizable monolayers have also been used to detect various signals (temperature change [204], pH change [205]) by the variation of redox cofactor regeneration rates (therefore by the control of enzymatic activity). Thus, they represent examples of biocatalytic switches. All the systems described above represent examples of bioelectronic devices that can be used for the trans-

duction of photonic signals into amperometric signals using electrically 'wired' enzymes. They can read out information written with light and amplify the signals using biocatalytic reaction cascades.

4.3 The Photochemical Activation of Enzymes

The biochemical processes performed by green plants and photosynthetic bacteria involve a primary photoinduced electron transfer that leads to charge separation and the formation of redox species. These redox species activate electron transfer to complex enzyme pathways that convert the energy of the separated charges into chemical energy that is used by plants and photosynthetic bacteria for their physiological needs. The photosynthetic apparatus in green plants is organized into two photosystems, photosystem I and photosystem II (PS-I and PS-II, respectively) schematically represented as the Z-scheme (Figure 29). Primary photoinduced charge separation in the both photosystems proceeds with the participation of chlorophyll and pheophytin molecules organized into complex assemblies. These units provide very fast and efficient vectorial electron transfer terminated by the formation of separated charges that can be stable at the final electron acceptor site for seconds. The reductive and oxidative equivalents generated during the primary photochemical step are then utilized in slow, dark enzymatic reactions. The first stable reduced product generated by PS-I is reduced ferredoxin, which induces a

Figure 29. Z-scheme of the photoinduced electron-transfer and dark enzymatic reactions operating in the photosynthesis of green plants. **Mn** = Mn-containing enzyme complex catalyzing water oxidation and O_2 evolution; Chl a and Chl b = photoactivated primary electron acceptors in photosystems I and II, respectively; A and I = primary electron donors in photosystems I and II, respectively; ADP = adenosine diphosphate; ATP = adenosine triphosphate.

series of electron-transfer reactions that ultimately reduce the natural cofactor NAD^+ to NADH . This reduced cofactor provides the electron source for CO_2 fixation to form carbohydrates in a complex sequence of enzyme-catalyzed transformations (the Calvin cycle). The chlorophyll photooxidized in the PS-I is reduced by an electron coming from PS-II via an electron transport chain consisting of a quinone (the final electron acceptor in the reaction center of the PS-II) and electron-transporting proteins (cytochrome, plastocyanin). The oxidized chlorophyll of PS-II mediates the biocatalyzed oxidation of water to molecular oxygen catalyzed by a complex Mn-containing protein. This scheme emphasizes that the photosynthetic apparatus operates by a synchronous mechanism involving a photochemical part, where light energy is converted to chemical potential by electron-transfer reactions, followed by a set of dark reactions utilizing the chemical energy in driving CO_2 fixation and O_2 evolution.

Significant progress has been accomplished in the understanding of photoinduced electron-transfer and charge-separation processes by the characterization of the stepwise electron transfer in the photosynthetic reaction centers isolated from the photosynthetic bacteria *Rhodobacter sphaeroides* R-26 [206]. In contrast to green plants, photosynthetic bacteria contain a single photosystem, consisting of a protein matrix with embedded pigments and electron relays (Figure 30). This assembly includes four bacteriochlorophylls (BChl), two bacteriopheophytins (BPhe), two ubiquinones (UQ) and a nonheme iron. These units are organized in an almost symmetrical spatial configuration consisting of two arms, labeled L and M. Two of the BChls in this assembly (the 'special pair') form the primary electron donor site. The remaining two BChls, two BPhe's and two ubiquinones occupy analogous positions in the L and M arms. Photoinduced electron transfer initiated by excitation of $(\text{BChl})_2$ proceeds only across arm L and involves sequential electron transfer to BChl_L , BPhe_L , UQ_L and UQ_M . The important charge-separated intermediates and their lifetimes are represented in Figure 30. A vectorial electron-transfer process

Figure 30. Charge-separated intermediates and their lifetimes in the bacterial photosynthetic reaction center.

proceeds in the photosynthetic reaction center and the lifetime of the intermediate redox products is lengthened as the distance between the components increases.

These photosynthetic reaction centers have been used for the construction of highly efficient photobioelectronic devices. The electrical ‘wiring’ of these natural photosensitive proteins (e.g., bacterial photosynthetic reaction centers [207]) on electrode surfaces results in electrodes that can be considered to be elements of photobioelectronic devices. More importantly, the study of photosynthetic reaction centers has resulted in a basic understanding of the mechanism of the photoinduced charge separation realized by nature. Specifically, photoinduced electron transfer in dye-functionalized proteins has been studied extensively and the kinetics of forward electron-transfer quenching and backward recombination have been characterized as a function of parameters including the free energy driving the electron transfer, the distance separating the donor–acceptor pair and protein structure [208–211].

4.3.1 Biological Transformations Driven by the Photochemical Regeneration of $\text{NAD(P)}^+/\text{NAD(P)H}$ Cofactors

As many redox enzymes depend on the common $\text{NAD(P)}^+/\text{NAD(P)H}$ cofactors, the development of photochemical regeneration cycles of these natural cofactors could provide a general means for the activation of numerous redox biotransformations. $\text{NAD(P)}^+/\text{NAD(P)H}$ -dependent enzymes usually operate reversibly. For example, Figure 31 outlines the biocatalyzed reduction of pyruvic acid (**21**) to lactic acid (**22**) by an alcohol in the presence of alcohol dehydrogenase and lactate dehydrogenase as well as NAD^+ cofactor. In an excess of lactic acid, however, the reverse process is possible and an equilibrium mixture of reactants and products is formed. This possibility can facilitate an ‘uphill’ endergonic process through the constant input of radiation energy. Thus, by the light-induced production of these cofactors the photosynthetic transformations may be envisaged [212–214].

Photochemical reductive systems providing regeneration of NAD(P)H

One photosystem for the reduction of NADP^+ to NADPH consists of *N,N'*-dimethyl-4,4'-bipyridinium (methylviologen, MV^{2+}) as an electron mediator,

Figure 31. The biocatalyzed conversion of pyruvic acid (**21**) to lactic acid (**22**) by an LDH–AlcDH system and the use of the NAD^+/NADH cofactor. The transformation proceeds with the oxidation of ethanol, and is reversed in a high concentration of lactic acid.

Figure 32. Photosensitized regeneration of NAD(P)H cofactor involving enzymes (FDR or LipDH) and the artificial electron-transfer mediator MV^{2+} , and using (A) $\text{Ru}(\text{bpy})_3^{2+}$ or (B) $\text{Zn}(\text{II})$ *meso*-(*N*-tetramethylpyridinium)porphyrin, Zn-TMPyP^{4+} , as a photosensitizer.

$\text{Ru}(\text{II})$ tris(bipyridine) [$\text{Ru}(\text{bpy})_3^{2+}$] as a photosensitizer, triammonium ethylenediaminetetraacetic acid [$(\text{NH}_4)_3\text{EDTA}$] as a sacrificial electron donor and the enzyme ferredoxin– NADP^+ reductase (FDR) [215, 216]. Oxidative electron-transfer quenching of the excited $\text{Ru}(\text{bpy})_3^{2+*}$ yields the *N,N'*-dimethyl-4,4'-bipyridinium radical cation (reduced methylviologen, $\text{MV}^{\cdot+}$), which mediates the reduction of NADP^+ in the presence of FDR as a biocatalyst (Figure 32A). The quantum efficiency for NADH production corresponds to $\phi = 1.9 \times 10^{-2}$. A related system that includes $\text{Zn}(\text{II})$ *meso*-(*N*-tetramethylpyridinium)porphyrin (Zn-TMPyP^{4+}) as a photosensitizer, mercaptoethanol as a sacrificial donor and lipoamide dehydrogenase (LipDH) as a biocatalyst has been applied for the photochemical reduction of NAD^+ to NADH (Figure 32B).

A different approach to the photochemical regeneration of NAD(P)H cofactors includes the integration of biomaterials with a semiconductor photocatalyst. Light-induced excitation of the semiconductor generates an electron–hole pair. While conduction-band electrons act as the electron source for the reduction of NAD(P)^+ to NADH, the valence-band hole oxidizes a solubilized donor. Heterogeneous semiconductor powders or colloids (TiO_2 , CdS) have been used to accomplish the photoreduction of the soluble electron mediator MV^{2+} in the presence of a sacrificial electron donor (e.g., mercaptoethanol or formate). Subsequent NADH regeneration was observed in the presence of LipDH [213, 217]. The direct coupling of an inorganic semiconductor with the active centers of NAD^+ -dependent enzymes is especially interesting as this could provide light-driven NADH regeneration without

Figure 33. Regeneration of NADH by a photochemical system consisting of CdS–hydrogenase (from *Alcaligenes eutrophus*) and using formate as a sacrificial electron donor.

the need for any exogenous mediator. This goal has been achieved using the NAD^+ -dependent hydrogenase from *Alcaligenes eutrophus* immobilized on CdS particles [218]. Photoregeneration of NADH in a system composed of NAD^+ , hydrogenase–CdS and formate was obtained via direct electron transfer from the semiconductor to the enzyme in the absence of any mediating electron carriers (Figure 33).

The regeneration of NADH cofactor for subsequent biocatalytic transformations can also be accomplished by nonenzymatic means. Photosensitized regeneration of NADH proceeds in the presence of various rhodium complexes such as Rh(III) tris(bipyridine) $[\text{Rh}(\text{bpy})_3^{3+}]$ and Rh(III) tris(2,2'-bipyridyl-5-sulfonic acid) $[\text{Rh}(\text{bpysa})_3^{3+}]$ [219, 220]. Single-electron reduction of the rhodium complex is accompanied by the subsequent disproportionation of the product, resulting in a two-electron reduced product in the form of a hydridorhodium complex, capable of reducing NAD^+ to NADH. For example, in the photosystem composed of $\text{Ru}(\text{bpy})_3^{2+}$ as a photosensitizer, $\text{Rh}(\text{bpy})_3^{3+}$ as an electron acceptor and triethanolamine (TEOA) as a sacrificial electron donor, NAD^+ was reduced to NADH by the stepwise mechanism outlined in Figure 34 [219]. The primary process in this system includes the oxidative quenching of the excited state of the photosensitizer by the rhodium complex, followed by the reduction of its oxidized state by TEOA. The reduced state of the rhodium complex participates in the reduction of NAD^+ via the intermediate formation of the hydridorhodium complex. A related system includes $\text{Rh}(\text{bpysa})_3^{3+}$ as an electron relay and hydride transfer catalyst, $\text{Ru}(\text{bpy})_3^{2+}$ as a photosensitizer and ascorbate as a sacrificial electron donor [220]. The primary process in this system is the reductive quenching of $^*\text{Ru}(\text{bpy})_3^{2+}$ by ascorbate resulting in the formation of the reduced state of the photosensitizer

Figure 34. Nonenzymatic photosensitized regeneration of NADH using $\text{Rh}(\text{bpy})_3^{3+}$ as an electron-transfer mediator.

$[\text{Ru}(\text{bpy})_3^+]$. This reduced species is oxidized by $\text{Rh}(\text{bpy})_3^{3+}$, resulting in the formation of the reduced hydridorhodium complex, which provides further reduction of NAD^+ . The NADH regenerated in this photochemical system was coupled with the enzymatic reduction of acetaldehyde to ethanol in the presence of alcohol dehydrogenase.

Photochemically regenerated NAD(P)H cofactors may be used to drive secondary reductive biocatalytic transformations [212, 216, 221]. In these cases, it is important to avoid interactions between the photosystems and the biocatalysts. For example, NADPH regenerated photochemically in the presence of the $\text{Ru}(\text{bpy})_3^{2+}$ and ferredoxin reductase has been utilized for the reduction of ketones, e.g., 2-butanone in the presence of alcohol dehydrogenase (AlcDH) or for the reductive amination of α -ketoglutaric acid to glutaric acid. In addition, NADH regenerated by $\text{Zn}(\text{II})$ -porphyrin in the presence of lipoamide dehydrogenase has been used for the reduction of pyruvic acid to lactic acid in the presence of lactate dehydrogenase (LDH) and for the reductive amination of pyruvic acid to alanine.

Photogenerated cofactors can be employed to drive biocatalytic enzyme cascades including the photosynthetic carbon dioxide fixation process [184] (Figure 35). Photogenerated NADPH provides a two-electron relay for the insertion of CO_2 into α -ketoglutaric acid (**23**) and pyruvic acid (**21**) in the presence of isocitrate dehydrogenase (IcDH) and malic enzyme (MalE), respectively. In these photo-systems, $\text{Ru}(\text{bpy})_3^{2+}$ acts as a photosensitizer, MV^{2+} as a primary electron acceptor and 2-mercaptoethanol as the sacrificial electron donor. Photogenerated MV^{+} mediates the regeneration of NADPH in the presence of FDR, and the resulting cofactor provides the electrons for the dark fixation of CO_2 into keto acids. The net process accomplished in these transformations corresponds to the reductive insertion of CO_2 into keto acids by the oxidation of the sacrificial thiol donor (Eq. 7):

Figure 35. The application of the light-induced regeneration of NADPH to drive the biocatalyzed CO₂ fixation process and secondary transformations.

The photochemical carboxylation of pyruvic acid by this process is endergonic by about $\Delta G^\circ = 11.5 \text{ kcal mol}^{-1}$ and represents a true 'uphill' photosynthetic pathway. The carbon dioxide fixation product can then act as the source substrate for subsequent biocatalyzed transformations. For example, photogenerated malic acid can act as the source substrate for aspartic acid (Figure 35). In this case, malic acid is dehydrated by fumarase (Fum) and the intermediate fumaric acid is aminated in the presence of aspartase (Asp) to give aspartic acid.

Photochemical oxidative systems providing regeneration of NAD(P)⁺

The photochemical regeneration of NAD(P)⁺ proceeds by one of two possible mechanisms: (a) the reductive quenching of a photosensitizer by NAD(P)H results in the formation of NAD(P)⁺ and the reduced state of the photosensitizer, that is subsequently oxidized by an electron acceptor (Figure 36A); (b) oxidative quenching of a photosensitizer by an electron acceptor results in the formation of an oxidized state of the photosensitizer that is capable of oxidizing NAD(P)H (Figure 36B) [212]. Organic dyes such as methylene blue (**24**) and *N*-methylphenazonium methylsulfonate (**25**) have been used as photosensitizers for the photochemical regeneration of NAD(P)⁺. These photosensitizers operate by the reductive quenching route in the formation of NAD(P)⁺. The photoreduced dyes are re-oxidized by O₂ (Figure 37) [222, 223]. The quantum efficiencies for NAD⁺ formation using **24** and **25** correspond to $\phi = 0.30$ and 0.28, respectively. The oxidations of ethanol and lactic acid to acetaldehyde and pyruvic acid biocatalyzed by alcohol dehydrogenase or lactate dehydrogenase, respectively, have been photochemically driven by the regeneration of NAD⁺.

The photolysis of organic compounds to molecular hydrogen and the oxidized organic products has been reported by photogeneration of NAD⁺ (Eqs. 8–13) [224]:

Figure 36. The photochemically induced oxidative regeneration of NAD(P)^+ cofactors: (A) when the primary step involves the reductive quenching of the photoexcited dye by NAD(P)H , and (B) when the primary step involves the oxidative quenching of the photoexcited dye by an electron acceptor.

Figure 37. The photosensitized regeneration of NAD(P)^+ cofactor using organic dyes **24** and **25** as photosensitizers, and the application of the NAD(P)^+ to drive enzymatic reactions.

The photochemical assembly includes Sn(IV) *meso*-(*N*-tetramethylpyridinium)-porphyrin, (Sn-TMPyP⁴⁺) as a photosensitizer, a Pt colloid as a heterogeneous catalyst, the reduced cofactor NADH, an organic photolyzable substrate (e.g., ethanol) and the respective NAD⁺-dependent enzyme (alcohol dehydrogenase). The primary step involves reductive electron-transfer quenching of the excited state of the metalloporphyrin (Eq. 9). The resulting products undergo redox transformations that ultimately lead to NAD⁺ (Eq. 11) and the hydrogenated porphyrin (Eq. 10). These two photoproducts drive the oxidation and reduction of the organic material: while H₂ evolution is effected by the hydrometalloporphyrin in the presence of the Pt catalyst acting as charge storage site (Eq. 12), NAD⁺ mediates the oxidation of the alcohol using AldDH as a biocatalyst (Eq. 13). All of the photo-system components are recycled and the net transformation corresponds to the endergonic ($\Delta G^\circ = 10 \text{ kcal mol}^{-1}$) cleavage of ethanol (Eq. 14):

Thus this energy storage transformation represents a photosynthetic process in which H₂ fuel is produced.

The photolysis of organic materials has also been accomplished by the oxidative quenching of photosensitizers. For example, oxidative quenching of Ru(bpy)₃²⁺ by MV²⁺ in the presence of NADH leads to MV^{•+} and NAD⁺ through the sequence of reactions outlined in Eqs. 15–17. The reduced photoproduct, MV^{•+}, mediates H₂ evolution in the presence of Pt colloid (Eq. 18), while NAD⁺ mediates the two-electron oxidation of ethanol (Eq. 19) or lactic acid (Eq. 20) biocatalyzed by the respective enzyme [225].

Figure 38. Biocatalyzed photosynthetic systems mediated by photochemically generated *N,N'*-dimethyl-4,4'-bipyridinium cation radical.

4.3.2 Enzymatic Reactions Driven by the Photochemical Regeneration of Synthetic Electron Relays

A variety of NAD(P)H-dependent enzymes recognize artificial electron carriers. These relays can substitute the native cofactors and activate electron-transfer reactions to the enzymes [212]. Photogenerated *N,N'*-dimethyl-4,4'-bipyridinium radical cation ($MV^{\bullet+}$) is recognized by various enzymes such as hydrogenase (Hyd) [226–228], formate dehydrogenase (FDH) [184], nitrate reductase (NitraR), nitrite reductase (NitriR) [229] and glutathione reductase (GluR) (Figure 38) [88b]. Various biocatalyzed photosynthetic systems using the light-induced regeneration of $MV^{\bullet+}$ by Zn-porphyrin, chlorophyll or $Ru(bpy)_3^{2+}$ photosensitizers and sacrificial electron donors such as EDTA (which may be in the form of any of a number of salts), cysteine and mercaptoethanol have been developed [184, 226–229]. For example, a photosystem composed of chlorophyll a (Chl) as a photosensitizer, MV^{2+} as an electron acceptor and ascorbate as a sacrificial electron donor has provided the photochemical reduction of MV^{2+} to $MV^{\bullet+}$. The resulting $MV^{\bullet+}$ can trigger H_2 evolution in the presence of hydrogenase [228]. Primary electron-transfer quenching reactions of $*Chl$ can be either oxidation by MV^{2+} or reduction by ascorbate depending on the pH of the medium [230]. Thus, different species can be involved in the formation of $MV^{\bullet+}$: the excited state of the photosensitizer ($*Chl$) or chlorophyll anion radical ($Chl^{\bullet-}$) in the case of oxidative or reductive quenching, respectively.

The reduction of carbon dioxide to formate in the presence of FDH represents a photochemical CO_2 -fixation process. In addition to $MV^{\bullet+}$, the enzyme recognizes other electron carriers such as 2,2'-bipyridinium radical cations [184]. Reduction of nitrate (NO_3^-) to nitrite (NO_2^-) and subsequently the reduction of nitrite to ammonia in the presence of NitraR and NitriR, respectively, allows the sequential $8e^-$

reduction of nitrate to ammonia in a photosystem that includes the two enzymes. The two enzymes are activated by photochemically regenerated MV^{+} . In a photosystem including $Ru(bpy)_3^{2+}$ as a photosensitizer, the fixation of NO_3^- to ammonia has been driven with a quantum efficiency of $\phi = 3 \times 10^{-2}$. Photobiocatalytic hydrogen evolution was achieved when hydrogenases were coupled to semiconductors and photosensitizers in the presence of artificial or natural electron carriers, usually MV^{2+} [226, 231]. It should be noted that hydrogenases isolated from mesophilic organisms are capable of evolving hydrogen in the presence of TiO_2 without electron carriers by direct electron transfer from the conduction band of the semiconductor to the enzyme [232].

For practical photoinduced synthetic biocatalyzed transformations, it is important to integrate biocatalysts in immobilized matrices that allow the recycling of the photosystems. The fact that bipyridinium sites act as electron mediators for various redox enzymes was used to develop two paradigms for the electrical contacting and photoactivation of the biocatalyst (Figure 39). By one approach, the bipyridinium electron relays are tethered by covalent bonds to the protein backbone (Figure 39A). These electron relays act as oxidative quenchers of the excited state of the dye and, upon photoreduction of the electron acceptor units, they act as electron carriers that activate the reductive functions of the enzyme. As an example, the

Figure 39. Electrical communication between an enzyme redox center and a photoexcited species attaining light-induced biocatalyzed transformations: (A) direct electrical 'wiring' of the protein by its chemical modification with tethered electron-relay units; (B) electrical communication by the immobilization of the protein into a redox-functionalized polymer matrix.

enzyme glutathione reductase was activated by the covalent tethering of *N*-methyl-*N'*-propionic acid-4,4'-bipyridinium (**4**) units to lysine residues of the protein backbone (Figure 39A) [233]. In a photochemical system composed of $\text{Ru}(\text{bpy})_3^{2+}$, EDTA and the bipyridinium-modified GluR, reduction of glutathione proceeds. Oxidative quenching of the photosensitizer by the tethered bipyridinium units results in the formation of bipyridinium radical cation units that mediate electron transfer to the enzyme active site that reduces the substrate. The oxidized photosensitizer, $\text{Ru}(\text{bpy})_3^{3+}$, takes an electron from the electron donor, EDTA, resulting in the recycling of the light-active compound.

By the second approach, the enzyme is immobilized in a redox polymer assembly (Figure 39B). Electron-transfer quenching of the photosensitizer by the polymer matrix generates an 'electron pool' for the activation of the enzyme. Photoreduction of nitrate to nitrite was accomplished by the physical encapsulation of NitraR in a redox-functionalized 4,4'-bipyridinium acrylamide copolymer [234]. In this photo-system, $\text{Ru}(\text{bpy})_3^{2+}$ was used as a photosensitizer and EDTA as a sacrificial electron donor. Oxidation of the excited photosensitizer results in electron transfer to the redox polymer, and the redox sites on the polymer mediate further electron transfer to the enzyme redox center, where the biocatalyzed transformation occurs. The rate constant for the MET from the redox polymer functionalities to the enzyme active site is $k_{\text{et}} = (9 \pm 3) \times 10^5 \text{ s}^{-1}$. Similarly, the enzyme glutathione reductase was electrically 'wired' by interacting the enzyme with a redox polymer composed of polylysine modified with *N*-methyl-*N'*-carboxyalkyl-4,4'-bipyridinium. The photosensitized reduction of oxidized glutathione (GSSG) (Eq. 21):

was examined in a photosystem composed of $\text{Ru}(\text{bpy})_3^{2+}$ as a photosensitizer, EDTA as a sacrificial electron donor, the redox-modified polylysine as an electron 'wiring' matrix and the enzyme glutathione reductase (GluR) [235]. The effectiveness of electrical communication between the excited species and the redox center was established as a function of the alkyl chain length bridging the bipyridinium salt to the polymer backbone. As the chain length tethering the bipyridinium relay to the polymer increases, electrical communication between the redox polymer and enzyme active site is enhanced since the redox group mediating electron transfer is more free to penetrate the protein active center.

Despite their advantages, the photobiocatalytic systems generally shown in Figure 39 still require diffusional components: the photosensitizer and sacrificial electron donor. Further efforts should be directed to the organization of photobiocatalytic systems where the photosensitizer is also immobilized in the matrix.

4.3.3 Photochemical Activation of Enzymes Using Dyes Covalently Tethered to the Protein Backbone

The covalent tethering of a photochemically active dye to a protein backbone can turn a native enzyme into a photoactive biocatalyst. Upon irradiation, the covalently

Figure 40. A biocatalytic reaction photochemically driven by the direct electron transfer from the photoexcited dye molecule covalently tethered to the enzyme backbone.

linked dye produces an excited state that is capable of transferring an electron to the enzyme active site. This induces a biocatalytic reaction at the reduced active site of the enzyme after which the active site is returned to the oxidized state. The initial ground state of the dye can be then regenerated in the presence of a sacrificial electron donor. This photochemically driven cyclic transformation results in the realization of a light-stimulated biocatalytic reaction (Figure 40). Glutathione reductase was transformed to a 'photoenzyme' by tethering photoactive eosin dye units (Eo^{2-}) to the protein [236]. The mechanism of the enzyme photoactivation is summarized in Eqs. 22–26:

The reaction scheme includes primary inter-dye electron-transfer quenching to yield the oxidized ($\text{Eo}^{\bullet-}$) and reduced ($\text{Eo}^{\bullet 3-}$) dye species both linked to the same protein (Eq. 22). The reduced dye stimulates electron transfer to the enzyme active site (Eq. 25) and the activation of the enzyme towards the reduction of oxidized glutathione (GSSG, Eq. 26). The oxidized dye species oxidizes EDTA (Eq. 23) and the two reactions regenerate the photoactive enzyme (Eqs. 25 and 26). Figure 41 shows the light-triggered activation of glutathione reductase for the reduction of GSSG.

Semi-synthetic enzymes are produced by the reconstitution of apo-proteins with artificial active sites that yield novel catalytic functions [237]. For example, reconstitution of apo-myoglobin with Co(II)-protoporphyrin IX results in a novel biocatalyst that is capable of hydrogenating acetylene derivatives or evolving hydrogen [209, 238]. By the modification of the reconstitution of apo-proteins with artificial redox-active cofactors and the covalent attachment of photosensitizer units, photo-

Figure 41. Rates of GSH formation under illumination at 475 nm. (a) $\text{Eo}^{2-}\text{-GR}$ (1 mg mL^{-1}), EDTA (10 mM), GSSG (10 mM); (b) a similar photosystem, but with the light switched on and off at the times indicated.

enzymes that stimulate photoinduced electron transfer and tailored biocatalytic transformations can be designed.

Apo-myoglobin was reconstituted with Co(II) -protoporphyrin IX and eosin dye units were tethered to lysine residues of the protein by the reaction of the Co(II) -protoporphyrin IX-reconstituted myoglobin with eosin isothiocyanate (**26**) [238]. The resulting eosin-functionalized, Co(II) -protoporphyrin IX-reconstituted myoglobin, $\text{Eo}^{2-}\text{-Mb-Co(II)}$, acts as a photobiocatalyst for H_2 evolution or the hydrogenation of acetylene to ethylene (Figure 42). Irradiation of $\text{Eo}^{2-}\text{-Mb-Co(II)}$ in an aqueous solution in the presence of EDTA yields H_2 evolution with a quantum yield of $\phi = 2 \times 10^{-4}$. Irradiation of the photobiocatalyst in the presence of acetylene and EDTA as sacrificial electron donor results in the hydrogenation of acetylene to ethylene with $\phi = 1 \times 10^{-2}$. The mechanisms that lead to the photoinduced H_2 evolution or the hydrogenation of acetylene are summarized in Eqs. 27–31:

Photoinduced electron transfer from the eosin dye to the Co(II) center yields a Co(I) species as an active site for the formation of a Co(III) hydride intermediate.

Figure 42. The preparation of a photoenzyme by the reconstitution of a heme protein with Co(II)-protoporphyrin IX and the chemical modification of the protein backbone with a tethered chromophore. Hydrogen evolution and hydrogenation of acetylene derivatives photobiocatalyzed by the assembly.

While the slow protonation of the hydride species leads to H_2 evolution, the ligation of acetylene to the Co(II)-protoporphyrin results in intramolecular hydride transfer and the hydrogenation of acetylene to ethylene. The oxidized dye is reduced by EDTA and thus the photobiocatalyst functions as a cyclic photoenzyme. Photoinduced hydrogenation of acetylenedicarboxylic acid proceeds stereoselectively and yields the thermodynamically less stable *cis* product, maleic acid.

Structurally defined photoenzymes for the hydrogenation of acetylene were tailored by the chemical modification of hemoglobin. The native hemoglobin tetramer was separated to the α -hemoglobin and β -hemoglobin units. The native hemoprotein fragments were then converted into the respective apo-proteins and further reconstituted with Co(II)-protoporphyrin IX. The eosin chromophore was tethered to the semi-synthetic protein by the coupling of eosin maleimide (**27**) to the cysteine-93 residue of Co(II)-protoporphyrin-reconstituted β -hemoglobin, $\text{Eo}^{2-}-\beta\text{-Hb}-\text{Co(II)}$, or to the single unknown lysine residue of Co(II)-protoporphyrin-reconstituted α -hemoglobin, $\text{Eo}^{2-}-\alpha\text{-Hb}-\text{Co(II)}$. The two chromophore-functionalized Co(II)-protoporphyrin IX-reconstituted hemoglobin units act as photocatalysts for the hydrogenation of acetylene [209]. In the presence of EDTA as a sacrificial electron donor, photoinduced hydrogenation of acetylene to ethylene by $\text{Eo}^{2-}-\alpha\text{-Hb}-\text{Co(II)}$ and $\text{Eo}^{2-}-\beta\text{-Hb}-\text{Co(II)}$ proceeds with quantum efficiencies of $\phi = 0.02$ and 0.004 , respectively. The mechanism that leads to the hydrogenation of acetylene by these two synthetic photoenzymes is identical to that described for the $\text{Eo}^{2-}-\text{Mb}-\text{Co(II)}$ photobiocatalyst.

The stabilization of the photogenerated redox products in the eosin-functionalized, Co(II)-protoporphyrin IX-reconstituted myoglobin, $\text{Eo}^{\bullet-}\text{-Mb-Co(I)}$, (slow charge recombination proceeds with the rate constant $k_b = 1.4 \times 10^5 \text{ s}^{-1}$) allowed the tailoring of an integrated photosynthetic reaction center that stimulates reductive and oxidative biocatalyzed transformations without the participation of any sacrificial component [209]. The reductive function of the photoenzyme $\text{Eo}^{2-}\text{-Mb-Co(II)}$ was coupled to that of lactate dehydrogenase (an oxidative enzyme) in the presence of *N*-aminomethylferrocenecaproic acid (**5**) as a diffusional electron mediator (Figure 43A). Steady-state irradiation of a photosystem composed of $\text{Eo}^{2-}\text{-Mb-Co(II)}$, LDH and **5** in the presence of acetylene and lactic acid results in the cyclic photoinduced hydrogenation of acetylene by lactic acid to yield ethylene and pyruvic acid, $\phi = 2 \times 10^{-3}$ (Figure 43B). The photogenerated redox species, $\text{Eo}^{\bullet-}\text{-Mb-Co(I)}$, exhibits sufficient stability against back electron transfer to allow the secondary reduction of acetylene by the Co(III)-hydrido intermediate and the concomitant oxidation of **5** by the oxidized dye. The oxidized electron mediator diffusionaly contacts LDH and oxidation of the biocatalyst active site activates the oxidation of lactic acid to pyruvic acid. This system may be further improved by the integration of its components to an electrically contacted rigid photosynthetic reaction center where the two biocatalytic components, LDH and $\text{Eo}^{2-}\text{-Mb-Co(II)}$, are covalently linked to each other and are modified with the tethered electron relay providing the electron transfer between them (Figure 43C). In fact, the photosynthetic transformation corresponding to the hydrogenation of acetylene by lactic acid that was accomplished in the artificial system, mimics the functions of the photosynthetic bacteria *Chloroflexus* [239].

The site-specific tethering of photoactive units to pre-designed protein mutants provides a means to control the photoinduced electron transfer and the stability of the photogenerated redox products. For example, artificial amino acids derivatized with bipyridyl units were incorporated into Cyt *c* and the Ru(II)-tris-bipyridine photosensitizer was anchored to the pre-designed ligand [240]. The effect of the structure of the resulting tethered hemoprotein assembly on the photoinduced electron transfer was characterized. Although Cyt *c* is inactive as biocatalyst, it acts as an electron-transfer cofactor for numerous redox enzymes [37, 38]. Also, the heme site of Cyt *c* might be reconstituted with other catalytically active metalloporphyrins or peripheral modification can result in its biocatalytic activity [241]. Thus, one envisages the future integration of Cyt *c* in other light-driven photosynthetic transformations.

4.3.4 Photochemical Activation of Semi-synthetic Enzymes Reconstituted with Non-natural Photosensitive Cofactors

A new strategy for the design of semi-synthetic proteins and enzymes bearing non-natural functional groups involves the replacement of the native cofactors by modified cofactors chemically linked to functional groups providing novel properties. This approach allows the placement of artificial groups at specific positions in close vicinity to the cofactor site [237]. The incorporation of photosensitizer-

Figure 43. (B) Rates of formation of products upon illumination of a photosystem composed of myoglobin reconstituted with $Co(II)$ -protoporphyrin IX and modified with eosin (0.11 mg mL^{-1}), LDH ($0.6 \text{ units mL}^{-1}$), **5** ($8 \times 10^{-3} \text{ M}$) and lactic acid ($1 \times 10^{-2} \text{ M}$) under an atmospheric pressure of acetylene: (a) rate of ethylene formation and (b) rate of pyruvic acid formation. (C) Hypothetical improved system for the same photobiocatalytic system, where the two enzymes and electron mediator are covalently linked.

electron acceptor units in protein matrices has several important advantages over simple molecular photosensitizer–electron acceptor assemblies. The incorporation of the donor–acceptor pair in a rigid protein assembly permits the spatial separation of the electron-transfer photoproducts. This structural separation stabilizes the photoproducts against back electron transfer, and thus allows the effective use of the photogenerated redox species in secondary biocatalyzed transformations. Furthermore, the man-made active-site in the protein assemblies provides a unique microenvironment for stereoselective and chiroselective photobiocatalytic transformations.

Various dyads consisting of a heme unit bridged with the photoactive molecule $\text{Ru}(\text{bpy})_3^{2+}$ such as **28**, **29**, **30** have been synthesized for the generation of photoactivated hemo-proteins [210, 242]. Apo-myoglobin was reconstituted with the Fe(III)-heme– $\text{Ru}(\text{bpy})_3^{2+}$ dyad $[\text{Ru}(\text{bpy})_3^{2+}\text{-Mb}]$. The resulting protein yields the deoxy-Mb with the Fe(II) state of the heme upon irradiation under argon with visible light ($\lambda > 450$ nm) and in the presence of EDTA as a sacrificial electron donor. The resulting reduced species was rapidly converted into oxy-Mb upon exposure to air, confirming that Fe(II)–Mb was indeed the photoproduct (Figure 44A). It should also be noted that the photogeneration of the oxy species was not significantly affected by O_2 even though oxygen is a quencher of photoexcited $\text{Ru}(\text{bpy})_3^{2+}$. This effect was attributed to the accelerated intramolecular electron transfer from $^*\text{Ru}(\text{bpy})_3^{2+}$ to the Fe(III)-heme rather than to O_2 in the $\text{Ru}(\text{bpy})_3^{2+}\text{-Mb}$ protein assembly. Myoglobin reconstituted with **29** and **30** showed almost the same efficiencies of the heme photoreduction, but the myoglobin reconstituted with **28** revealed a substantially lower rate of photoreduction, demonstrating that the length of the spacer bridging the donor–acceptor pair has a significant effect on the photoreduction efficiency. Laser flash photolysis experiments have identified the electron-transfer mechanism in these systems [243]. It was concluded that the oxidative quenching of the excited state $^*\text{Ru}(\text{bpy})_3^{2+}$ ($E^\circ = -1.04$ V vs. SCE) by the Fe(III)-heme yields the redox photoproducts consisting of Fe(II)-heme and $\text{Ru}(\text{bpy})_3^{3+}$ and the oxidized species is reduced by the sacrificial electron donor. This process allows accumulation of the reduced photoproduct under continuous irradiation.

Photoinduced electron-transfer in the opposite direction was demonstrated upon irradiation of the $\text{Ru}(\text{bpy})_3^{2+}\text{-Mb}$ system in the presence of $\text{Co}^{3+}(\text{NH}_3)_5\text{Cl}$ as a sacrificial electron acceptor (Figure 44B) [244]. The photochemical reaction results in the formation of ferryl species (i.e., Fe(IV)-heme), with the intermediate formation of the porphyrin cation radical (as demonstrated using laser flash photolysis [237]). The electron-transfer cascade includes the primary oxidative quenching of the excited chromophore, $^*\text{Ru}(\text{bpy})_3^{2+}$, by $\text{Co}^{3+}(\text{NH}_3)_5\text{Cl}$ to yield $\text{Ru}(\text{bpy})_3^{3+}$ ($E^\circ = +1.01$ V vs. SCE). The resulting oxidant efficiently takes an electron from the porphyrin ring ($k_{\text{et}} = 8.5 \times 10^5 \text{ s}^{-1}$) and the porphyrin cation radical produced further oxidizes the central iron atom, converting it from the Fe(III) state to the Fe(IV) state ($k_{\text{et}} = 4.0 \times 10^4 \text{ s}^{-1}$ at pH 7.5).

An alternative approach to the preparation of ‘photoenzymes’ by the reconstitution of apo-proteins includes the application of metalloprotoporphyrins such as Zn(II)-protoporphyrin IX (Zn-P), which exhibits photophysical electron-transfer properties for the reconstitution of apo-proteins derived from hemoproteins. Func-

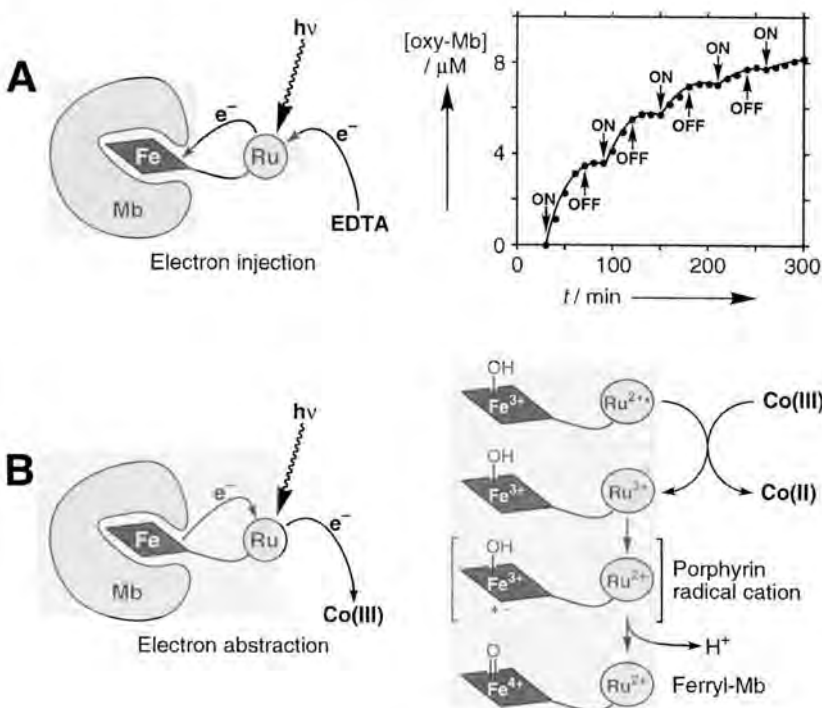

Figure 44. (A) Photoinduced electron transfer and ‘ON–OFF’ photoswitching of Ru(bpy)₃–Mb between the deoxy- and the oxy-heme states. Visible light ($\lambda > 450$ nm) results in switching according to the arrows. Adapted from Ref. [237] with permission. (B) Photooxidation of Ru(bpy)₃–Mb in the presence of a sacrificial Co(III) complex.

tionized Zn(II)-protoporphyrin–electron acceptor dyads such as **31** or **32** have been used to reconstitute apo-myoglobin [211, 245]. Vectorial photoinduced electron transfer proceeds in the semi-synthetic proteins, and the systems mimic functions of the photosynthetic reaction center. For example, in the Zn(II)-protoporphyrin IX–bis-viologen-reconstituted myoglobin, the vectorial electron transfer shown in Figure 45 and summarized in Eqs. 32–35 occurs:

Figure 45. Reconstitution of apo-myoglobin with a Zn-protoporphyrin IX linked covalently to an electron acceptor (31 or 32) and vectorial photoinduced electron transfer in the assembly.

The excited triplet state of the Zn(II)-protoporphyrin IX, ${}^1\text{Zn-P}$, is quenched by the covalently linked viologen with $k_q = 1.55 \times 10^6 \text{ s}^{-1}$, resulting in charge separation, Eq. 32. The protein matrix spatially separates the primary redox products, resulting in a slow intermolecular recombination process ($k_b = 1.3 \times 10^6 \text{ s}^{-1}$), Eq. 33, thus allowing the reduction of the secondary electron acceptor $[\text{Ru}(\text{NH}_3)_6^{3+}]$ ($k_{et} = 6.5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$), Eq. 34. The oxidized photosensitizer $\text{Zn-P}^{\bullet+}$ and the reduced acceptor $\text{Ru}(\text{NH}_3)_6^{2+}$ exhibit long lifetimes (ca. 2.6 ms), and are effectively stabilized against back electron transfer (Eq. 35) owing to the electrostatic repulsion of $\text{Ru}(\text{NH}_3)_6^{2+}$ from the positively charged protein interface.

The reconstituted photoactive proteins may act as light-triggered cofactors, activating enzyme cascades. For example, the electron-transporting protein cytochrome

Figure 46. Interprotein photo-induced electron transfer in a system composed of positively charged cytochrome *c* and myoglobin reconstituted with Zn-protoporphyrin IX covalently bound to a negatively charged 'comb' providing association of the proteins in the assembly.

b_{562} was reconstituted with the Fe(III)-protoporphyrin IX–Ru(bpy)₃²⁺ dyad [246]. Photoirradiation of the system in the presence of a sacrificial electron donor results in the reduced Fe(II)-protoporphyrin site. In the presence of Cyt *c*, inter-protein electron transfer occurs, and the latter hemoprotein is reduced. Using a related approach [247], apo-myoglobin was reconstituted with the photoactive Zn(II)-protoporphyrin IX covalently linked to a negatively charged 'molecular comb' (**33**). Electrostatic association of the positively-charged Cyt *c* to the 'comb' aligns the hemoprotein, and vectorial electron transfer from the excited photosensitizer to the heme site of Cyt *c* is facilitated in the inter-protein complex (Figure 46).

4.3.5 Applications of Photoactivated Redox Enzymes

The major advantage of photoactivated redox enzymes is their ability to drive endergonic 'uphill' photosynthetic transformations, and therefore to transform light energy into chemical energy. The use of redox proteins in such artificial photosynthetic systems has several advantages. Evolutionally optimized enzymes promise superior catalysts for the fuel generation process. This is particularly true for multi-electron-transfer processes such as CO₂ or N₂ fixation. The tailoring of efficient catalysts for these multi-electron-transfer reactions, particularly catalysts operating in aqueous media, is still a challenging topic for future research. Polyfunctional redox-substituted proteins provide an attractive catalytic alternative for such photosynthetic transformations. In addition to the ability to drive photosynthetic transformations, the high efficiency of native biocatalysts is a major advantage as the effective utilization of the photogenerated redox species eliminates back electron-transfer reactions. An interesting photochemically induced photosynthetic transformation is the light-driven synthesis of formate in a photoelectrochemical cell consisting of a p-InP cathode (Figure 47) [248]. Photoexcitation of the semicon-

Figure 47. Photosystem for the reduction of CO_2 by FDH, powered by the photoexcitation of electrons in a p-InP cathode and mediated by MV^{2+} .

ductor results in the transfer of conduction band electrons to the *N,N'*-dimethyl-4,4'-bipyridinium electron acceptor (MV^{2+}). The resulting reduced acceptor ($\text{MV}^{\bullet+}$) acts as an electron carrier that activates formate dehydrogenase (FDH) for the reduction of CO_2 to formate. A further advantage of photoactivated enzymes is their ability to stabilize electron-transfer photoproducts by means of their spatial separation by the rigid protein assembly. This suggests that the tailoring of donor–acceptor components, e.g., a photosensitizer–electron relay, within a protein assembly could lead to improved photoelectrochemical cells. The use of photoenzymes as biocatalysts for photosynthetic transformations may have a future in stereoselective synthesis. One may envisage the photosynthesis of feedstocks from abundant raw material using cascades of biocatalytic transformations.

4.4 Conclusion and Perspectives

Substantial progress in the understanding of electron-transfer in proteins has led to the development of two interconnected research fields involving the electrochemical and the photonic activation of redox proteins (bioelectronics and optobioelectronics). Electroactivated and photoactivated redox proteins might find broad applications in various fields. Table 2 summarizes some of these potential uses. The tailoring of electrical contact between redox enzymes and electrodes provides a basis for electrochemical biosensors. Besides the broad application of electrically contacted enzyme electrodes for the amperometric analysis of enzyme substrates, one may apply electrically contacted enzymes as redox labels for the sensing of biorecognition events such as antigen–antibody [249] or oligonucleotide–DNA [250] complexation. The use of electrobiocatalytic electrodes as active components of biofuel cells is also appealing. In particular, the development of catalytic electrodes that can drive the reduction of O_2 to water may contribute important interfaces for biological or chemical fuel cell elements [192]. An important future direction for the application of electrically ‘wired’ enzyme electrodes is electrosynthesis. Efficient stereoselective synthesis is envisaged at these electrodes. The ability to design redox-active proteins exhibiting vectorial electron transfer and electrosynch-

Table 2. Potential applications of electroactivated and photoactivated redox proteins.

Type	Activated function	Field of application
Electroactivated redox proteins	1. Electrical communication with electrodes and the amperometric transduction of biorecognition	Biosensors, analytical tools for clinical diagnostics, environmental analyses, food control, etc.
	2. Activation of electrobiocatalytic processes	Electrobiocatalytic synthesis; stereoselective synthesis Biocatalytic electrodes for biofuel cells
	3. Vectorial electron transfer; switchable electron transfer; amplified electron transfer	Development of biomolecule-based electronic devices such as diodes, switches, amplifiers
	4. Photonic activation of electrobiocatalytic functions of redox proteins and the electrochemical transduction of recorded photonic signals	Information storage and design of write-read-erase functions Biomaterial-based electronic elements such as photoelectronic switches, amplifiers, actinometers Photolithographic patterning of surfaces by light-induced activation of redox processes
Photoactivated redox proteins	1. Photoinduced electron transfer and charge separation	Conversion of light energy to electrical energy; development of photo-electrochemical cells Light-driven photosynthesis; stereo-selective synthesis
	2. Photochemical activation of redox enzymes by the generation of cofactors or electron carriers	Endoergic photosynthesis of fuel products; CO ₂ fixation; N ₂ fixation; photolysis of water

able electron transfer suggests that such systems could act as electronic elements in future biomaterial-based devices.

All these bioelectrocatalytic functions of redox proteins are based on the control and enhancement of the electrical communication between the redox sites of the proteins and the electrode support. This is accomplished by the nano-engineering of the surfaces with covalently anchored proteins, the structural alignment of the proteins on the electrodes and the chemical modification of the proteins with redox-active units. Preliminary results suggest that two approaches will play important roles in the future development of bioelectronic systems: (i) protein mutagenesis with specific functional amino acid residues that can align the protein on the electrode surface and control the electrical contact with the electrode; (ii) the synthesis of de novo proteins with tailored bioelectronic and electrobiocatalytic functions.

The photonic activation and deactivation of the electrobiocatalytic functions of enzymes represent a challenging future perspective of redox proteins. The photonic activation of a redox enzyme provides a means to detect the light signal by the electrobiocatalyzed process and its resulting current. The 'ON' and 'OFF' photo-

triggered biocatalyzed transformations in these systems will allow their future development as optical storage systems, biomaterial-based computers and light-signal detectors. Furthermore, the photonic activation of redox enzymes may be applied to generate patterns on surfaces. The light-induced biocatalytic reduction of metal ions on surfaces may be used as a means to generate micro- or nano-scale electric circuits.

Photoactivated redox proteins will play important roles in the future development of artificial photosynthetic systems. The unique participation of the protein matrices in photoinduced charge separation and the possibility of implanting catalytic sites in the protein indicate that tailored photoenzymes will be important components for the light-driven synthesis of fuels and valuable chemicals, e.g., CO₂ and N₂ fixation and amino acid synthesis. The areas of bioelectronics and optobioelectronics represent exciting interdisciplinary ventures for chemists, biologists, physicists and materials scientists. The advances in these fields offer compelling opportunities for the development of electronic biomaterial-based devices.

5 Interprotein and Intraprotein Electron Transfer Mechanisms

Gordon Tollin

5.1 Introduction

Protein electron transfer (ET) reactions are important components of a wide variety of key biological processes, including photosynthesis, respiration, nitrogen fixation, steroid biosynthesis, DNA biosynthesis, chemical carcinogenesis and drug detoxification. Many genetic diseases result from redox protein defects. ET reactions generally occur within either transient or pre-existing protein–protein complexes, in which the redox centers (heme, flavin, iron–sulfur, copper, etc.) can communicate either directly via orbital overlap, or indirectly via ligands or adjacent amino acid side-chains.

The field of biological electron transfer has undergone an enormous revitalization over the past decade or so, due both to theoretical and to experimental advances. Among the most significant developments [1] are the following:

- 1) Applications of Marcus ET theory [2] and the creation of theoretical methods for evaluating ET ‘pathways’ [3–5] have greatly enriched our understanding of protein-mediated ET mechanisms, and have provided a conceptual framework for describing these reactions. Marcus theory factors the ET process into electronic coupling matrix elements (H_{AB}), which describe the interactions between donor/acceptor electronic wave functions, and Franck–Condon terms, which describe nuclear motions required to reach the ET transition state, i.e., the crossover point between donor and acceptor potential energy surfaces. The pathways concept assumes that electrons ‘tunnel’ between localized redox centers, utilizing both through-bond and through-space routes which are highly sensitive to molecular structure. Although, in principle, quantum mechanical methods can be used to describe these processes, such applications to large and complex protein molecules are difficult [5].
- 2) High-resolution X-ray structures are now available for several multicenter ET proteins [6–9], as well as for redox protein–protein complexes [10–12]. These

have allowed many new questions to be asked regarding the detailed interplay between functional properties and 3-D structures.

- 3) New techniques have been developed for *directly* following intra- and inter-protein ET reactions in real time. These are based mainly upon photochemical methods for injecting or extracting electrons, and utilize laser flash photolysis and time-resolved spectrophotometry [13–16]. For interprotein reactions, this methodology permits the separation of protein–protein binding and ET processes, thus providing much more insight into structure–function relationships than can be obtained from steady-state kinetic analysis. This is especially true when this technology is combined with site-specific mutagenesis (see below).

Some of the important questions in this field, all of which are currently under intensive study in various laboratories, are the following. (i) What are the relative roles of electrostatic forces, hydrogen bonding and hydrophobic interactions in stabilizing intermediate complexes and in determining protein–protein orientations during ET? (ii) Which amino acid side-chains participate in complex formation and ET, and how do they function? Are π orbitals and hydrogen bonds directly involved in electron flow? To what extent do through-bond and through-space mechanisms contribute? Are specific charge pairs required, or are generalized electrostatic fields involved? (iii) How important is intermolecular orientation? Are multiple complexes involved, or is there a single, highly specific orientation required for optimal ET? (iv) What is the role of molecular dynamics in complex formation and ET? (v) Are highly specific (single or multiple) pathways utilized for ET? (vi) What are the quantitative relationships between ET rate constants, redox potentials and distances for both interprotein and intraprotein reactions?

According to the classical Marcus theory for weakly coupled (nonadiabatic) systems, the potential energy curves of reactants and products are modeled as intersecting simple harmonic oscillators, and the ET rate constant (k_{ET}) has a parabolic dependence on the free energy of the reaction. An optimum value (whose magnitude is determined by H_{AB}) is achieved when the free energy equals the reorganization energy (λ). The latter parameter reflects the energy required for rearranging the reactant nuclei and surrounding water molecules in order for ET to proceed, i.e., to achieve the geometry corresponding to the potential minimum of the products. Note that a hydrophilic active site will generally result in a larger λ than a hydrophobic one as a consequence of polarity changes resulting from the electron transfer process. The region beyond this optimum, in which k_{ET} decreases with increasing driving force, is referred to as the ‘Marcus inverted region’. According to Marcus theory, the distance dependence should be exponential, and it has been suggested that this is the dominating factor in protein ET reactions [17]. In contrast, the tunneling-pathway concept [5] emphasizes the importance of the relative coupling strengths of various through-bond (including hydrogen bonds) [18] and through-space routes between redox centers, rather than a linear through-space distance. Parameterized methods for calculating the effectiveness of these routes have been developed [5]. It should be noted that, because of the uncertainties involved in specifying the protein–protein contacts occurring in a transient intermediate complex, the application of the pathways formalism to interprotein ET is

considerably more difficult than for intraprotein reactions. Furthermore, protein conformational changes coupled to ET can introduce significant complications.

It is clear based on the present literature that we are far from having a satisfactory understanding of biological ET. Thus, the correlations between reaction rates, redox potentials and distance that are expected from simple Marcus theory are not always observed (for examples, see Refs. [17] and [19–25]). Furthermore, in many cases the detailed structure and composition of the intervening medium between redox centers must be taken into account [13, 24], which is often difficult to do. This lack of understanding is dramatically illustrated by the following example. In the three flavocytochromes for which crystal structures are available [6, 8, 9], the angle between the flavin and heme planes varies between 0° and 60°, the regions of the flavin ring through which ET apparently occurs differ substantially and the driving forces are different. As yet, no rationale is available for correlating the observed inter-prosthetic group k_{ET} values with these properties [9, 25].

Additional areas that are in serious need of further clarification involve the roles of electrostatics and of ET pathways. Thus, although electrostatic forces are clearly involved in complex formation and ET, there is growing evidence for the importance of hydrophobic interactions [26] and of dynamic rearrangements following initial collisions in which long-range electrostatic forces have pre-oriented the diffusing molecules [27–29]. Additionally, the relative importance of generalized electrostatic potentials and/or specific charge pairs is not always clear. Finally, although specific pathways for ET are often invoked [5, 30], it is difficult to assess experimentally the importance of one pathway over another in physiologically relevant systems [31]. Even when the structures of crystalline protein–protein complexes are known [11, 12], it must still be proven that these represent actual ET intermediates along the reaction pathway. Thus, lattice forces could selectively stabilize one of several structures present in solution, and not necessarily the most competent one for ET. Present information is sketchy. For the methylamine dehydrogenase system, slow ET has been observed in crystalline binary and ternary complexes of the participating proteins [32]. Crystals of a cytochrome c_2 –bacterial photosynthetic reaction center complex have comparable activity to that observed in solution, although a high-resolution structure for the complex was not obtained [33]. The crystal structures of binary complexes between two c -type cytochromes and cytochrome c peroxidase have been solved to high resolution [10], and an earlier computer model of one of the complexes was formulated based on maximizing electrostatic interactions between the two proteins [34]. These structures are very different; experiments indicate that the computer-generated structure is irrelevant to ET, and that the structures of the crystalline complexes are only partially relevant. The latter point will be discussed further below. Finally, for systems in which two or more redox cofactors are present within a single polypeptide chain organized into two or more domains, it may not be true that the structure of the fully oxidized protein accurately reflects the structures of partially reduced intermediate states or of variously liganded states. Examples of this will be described below.

Several redox protein systems have proven valuable as probes of these various questions. The main prerequisites for such models are the existence of a high-resolution 3-D structure for the reaction participants, the ability to express re-

combinant proteins at high levels and to carry out site-specific mutagenesis, and the ability to directly observe the individual steps involved in inter- and intraprotein ET. Among the most intensively studied systems are the following: (1) *interprotein*, ferredoxin–ferredoxin:NADP⁺ reductase; cytochrome *c*–cytochrome *c* peroxidase; cytochrome *f*–plastocyanin; (2) *intraprotein*, flavocytochrome *b*₂ (yeast lactate dehydrogenase); sulfite oxidase; cytochrome P450BM-3. In the following sections we will discuss these systems in some detail in order to illustrate the present state of our knowledge of the mechanisms of protein ET reactions.

5.2 Experimental Methods for Investigating Protein ET Reactions

In this section, we will briefly review some of the key techniques that have allowed the attainment of new levels of insight into inter- and intraprotein ET processes. Although our attention will be limited to kinetic methodology, this is not meant to imply that other approaches (e.g. spectroscopy) are not also of value.

5.2.1 Time-resolved Spectrophotometry

Although ET processes between redox centers can in principle be monitored by time-resolved spectrophotometry, a major requirement for the application of such methodology is the ability to synchronize observation with reaction progress. In the photosynthetic system, which is the paradigm for the use of time-resolved spectral methods to elucidate ET mechanisms, this is made possible by the fact that light absorption by chlorophyll molecules initiates the injection of electrons into the transport pathway, a process that occurs exceedingly rapidly (picoseconds). Thus, pulsed laser excitation can be used as the triggering event, and the progress of electrons through the various carriers can be observed by a variety of spectroscopic signatures. It is possible to mimic this in nonphotobiological redox systems [14, 25, 35–40] by utilizing the well-known excited state chemistry of riboflavin and its analogs as the means of reaction initiation. Flavin photoexcitation can be used to generate strong reductants or oxidants, which can either inject or remove electrons from the system under study.

Primary photochemical processes

The lowest triplet state of flavins (³F) can be populated in a few nanoseconds via intersystem crossing (ISC) from the first excited singlet state (¹F), and is a strong oxidant, capable of removing single H atoms or single electrons from a variety of molecules. Triplet state formation has a high quantum efficiency; for example, in the case of riboflavin, approximately 70 % of the absorbed photons generate the triplet species. The redox properties of the flavin triplet can be utilized either to produce a strong reductant, i.e., the neutral flavin semiquinone (FH[•]), by hydrogen

atom transfer from a sacrificial donor (AH_2), or to remove an electron from a reduced redox protein (P_{red}) to generate the anionic flavin semiquinone ($\text{F}^{\bullet-}$). These reactions are illustrated by the following equations:

Reactions 2 and 3 are generally diffusion-controlled, and thus can be made to occur on the microsecond time-scale. The exact time course depends upon the magnitude of the second-order rate constants for these reactions and the concentrations of AH_2 or P_{red} . Since the latter species are usually in large excess, these reactions follow pseudo-first-order kinetics. If EDTA (or similar donors) is used as the reactant in Eq. 2, the AH^\bullet species that is formed is highly unstable and rapidly ($\ll 1$ ms) undergoes decarboxylation, followed by reduction of an additional molecule of oxidized flavin to generate another neutral flavin semiquinone FH^\bullet , and fragmentation to produce stable products [41]. The flavin anion semiquinone ($\text{F}^{\bullet-}$) formed in reaction 3 will equilibrate, depending upon the pH and its pK_a , with the neutral semiquinone species (for example, the pK_a for riboflavin semiquinone is 8.4). The flavin semiquinones are kinetically unstable and are also strong reductants (at pH 7, the one-electron reduction potential for riboflavin semiquinone is -230 mV and that for 5-deazariboflavin semiquinone is -650 mV). Thus, in the absence of any other reducible species, the semiquinone will disproportionate to form oxidized and reduced flavin (Eq. 4), or, in the presence of an oxidized redox protein, will transfer a reducing equivalent to the protein prosthetic group (Eq. 5):

Reactions 4 and 5 are, of course, in competition with one another. Thus, if the concentration of P_{ox} is high enough, reaction 5 will predominate. However, one must keep this competition in mind in interpreting experimental data. An additional complication can arise due to the fact that FH_2 is also a strong reductant (at least in the case of ordinary flavins; with deazaflavins, the FH_2 species is much less reactive [42]). As a consequence, at low P_{ox} concentrations, a secondary protein reduction can occur via FH_2 , which contributes to the overall kinetics and must also be taken into account. This additional reaction can usually be recognized by two properties, i.e., it is slower than the initial reduction, and its amplitude diminishes with increasing protein concentration, which forces reactions to occur via the semiquinone. A similar complication occurs in the protocol of reaction 3; thus, the initial protein oxidation reaction generates a stoichiometric amount of flavin semiquinone, which can then react further via Eqs. 4 and 5. Again, however, this occurs on a much slower time scale than reaction 3, and can usually be readily deconvoluted. By

monitoring these reactions as a function of protein concentration, accurate values for the second-order rate constants for reactions 3 and 5 can be determined.

Although the ET processes represented by reactions 3 and 5 are nonphysiological, they can provide useful information. Thus, by varying the structure of the flavin it is possible to probe the steric and electrostatic environment of a protein redox center [38, 39]. This can be used as a method for assessing functional relationships between members of a homologous series of redox proteins (kinetic taxonomy). It is also possible to use these reactions to test the functional integrity of a redox center in a site-specific mutant [43].

Some additional features of the methodology are also worthy of note. (i) The intensity of the pulsed laser that is used to initiate the photochemistry is purposely kept low, so that substoichiometric quantities of flavin triplet and semiquinone are generated relative to the redox protein. This assures that pseudo-first-order conditions apply, and that only a single electron can be removed or added to each protein molecule. (ii) The irradiated volume in the sample cell is kept small ($<1\%$ of the total volume) so that only minor net conversion to products occurs. This allows samples to be subjected to multiple flashes for signal averaging and for the determination of protein concentration dependences by adding aliquots of protein to the sample. (iii) Because the oxidant and/or reductant are generated exogenously, no chemical modification of the protein is necessary. This last point is of some interest because it also provides one of the limitations of this methodology, i.e., since the initiation process depends upon *bimolecular* chemistry (reactions 2, 3 and 5), in some cases this becomes the major factor controlling the time resolution of the experiment. Another limitation of the present methodology derives from the fact that light absorption is used to initiate the reaction. Thus the wavelength range over which observation can be made without perturbing the sample is necessarily proscribed by this fact. The first of these limitations can be obviated by covalent attachment of the photoinitiator to a redox protein [13, 15, 16]. This allows a unimolecular process to be used to inject electrons, which achieves more rapid reaction initiation. However, this approach presents additional problems associated with the possibility of introducing structural perturbations into the system caused by the chemical modification. The second limitation, although intrinsic to all photochemical methodologies, is not a problem when high-energy radiation is used as the means of generating the initial electron donor or acceptor. Again, however, such pulse radiolysis procedures have their own unique difficulties, primarily associated with the exceedingly high reactivity (and therefore low specificity) of the free radical species formed under the conditions of the experiment. As is always true, one must accept trade-offs in using any of these procedures, and therefore each of them has a place in the armamentarium of the redox biochemist.

Intraprotein electron transfer reactions

If the reduced protein that is present in reaction 3, or the oxidized protein in reaction 5, has more than one redox center (denoted by A and B below, with the assumption that reaction occurs initially at site A), subsequent intraprotein ET processes can occur. This is shown in Eqs. 6a and 6b for oxidation and reduction

reactions, respectively:

This, of course, is subject to both thermodynamic and kinetic constraints. Specifically, the initial reaction must occur predominantly (although not necessarily exclusively) at the center having the appropriate redox potential (the higher potential for reaction 6a and the lower potential for reaction 6b), and rapidly enough so that the secondary transfers shown in these equations are observable.

Interprotein electron transfer reactions

If a second redox protein is present under the conditions represented by Eq. 3 or 5, secondary protein–protein ET reactions can occur, again subject to thermodynamic and kinetic constraints. In this situation, however, the constraints can be modulated by having the higher potential (under oxidizing conditions) or lower potential (under reducing conditions) protein present in stoichiometric excess, thereby favoring removal of electrons from (or entry of electrons into) the appropriate protein in the initial reaction with exogenous flavin.

By varying the concentration of the higher potential protein, a second-order rate constant for the interprotein reaction can be obtained. In a situation in which the reaction proceeds via an intermediate complex, as shown by the (minimal) mechanism in Eq. 7, non-linear concentration dependences may be observed:

Data obtained under these conditions can be fitted using a least-squares procedure based upon the exact solution to the differential equations describing this mechanism [37, 44]. This yields values for the complex dissociation constant K_D and the limiting first-order rate constant k_{ET} (a minimum value for the second-order rate constant for complex formation can also be obtained from this analysis). Note that K_D refers to the interaction between reduced P^1 and oxidized P^2 , a situation that is observable *only* by kinetic methodology.

5.2.2 Use of Ionic Strength to Probe Electrostatic Interactions

Inasmuch as soluble proteins generally have highly charged surfaces, it is to be expected that electrostatic interactions play an important role in controlling ET reactions, especially those that occur between individual protein molecules. The dependence of reaction rate constants on the ionic strength of the solvent environment has long been used to probe such interactions for small-molecule systems [45]. However, the point charge approximation inherent in most theoretical models is inappropriate for protein molecules that have large radii and multiple charges asymmetrically distributed on their surfaces. An alternative approach [46], based on experimental observations indicating that localized charges near the active site are

generally the most important determinants of electrostatic interactions in protein ET reactions (see below), is the so-called ‘parallel plate’ model. This approximates the actual charge distribution in the region of intermolecular contact during an interprotein ET reaction by uniformly charged parallel plates of net charge Z , radius ρ and separation r_{12} , and uses averaged values for the dielectric constants and dipole moments within this region. This analysis results in the following relationship between the observed bimolecular rate constant k and the ionic strength I :

$$\ln k(I) = \ln k_{\infty} - V_{ii}X(I) - V_{id}Y(I)X(I) - V_{dd}Y(I)^2Z(I) \quad (8)$$

where k_{∞} is the diffusion-controlled rate constant at infinite ionic strength and the individual V terms correspond to monopole–monopole, monopole–dipole and dipole–dipole interactions, respectively. The latter quantities depend on the interaction domain radius, on the active site charges, on the distance between the charged plates, on the protein dipole moments and on the dielectric characteristics of the protein interior, the protein surface and the interprotein region (see [46] for details). The total electrostatic interaction energy is given by

$$V_{el} = kT(V_{ii} + V_{id} + V_{dd}) \quad (9)$$

The ionic strength dependence of the rate constant is completely contained within the X , Y and Z terms. Eq. 8 allows a non-linear least-squares fitting of experimental data to be carried out, yielding values for k_{∞} and V_{el} . In practice, the monopole and dipole terms cannot be uniquely characterized by this procedure, and using only the V_{ii} term in the fitting procedure yields a satisfactory value for V_{el} .

Figure 1 shows a typical example of results obtained using this procedure for two nonphysiological interprotein ET reactions involving reduction of spinach plastocyanin by reduced *c*-type cytochromes [28]. Cytochrome c_{555} has a net positive electrostatic charge, and displays an attractive electrostatic interaction during ET with the net negatively charged plastocyanin. The theoretical fit to the parallel plate model yields a value for V_{el} of $-10.9 \text{ kcal mol}^{-1}$ and $k_{\infty} = 3.9 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$. In contrast, cytochrome c_{551} has a net negative charge, and shows a repulsive electrostatic interaction during ET. In this case the theoretical fit yields $V_{el} = 6.3 \text{ kcal mol}^{-1}$ and $k_{\infty} = 2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$. Although not shown here, the ionic strength dependence for the reaction of horse cytochrome *c* with plastocyanin yields a value for V_{el} of $-16.8 \text{ kcal mol}^{-1}$ and $k_{\infty} = 5 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$. It is interesting that, whereas the relative magnitudes of the V_{el} terms correlate well with the net protein charges, the k_{∞} values do not correlate with the relative thermodynamic driving forces for these reactions. Thus, the reduction potentials for the cytochromes are 145 mV for cytochrome c_{555} and 270 mV for both cytochrome c_{551} and horse cytochrome *c*. This would argue that other factors such as distance and orientation must be dominant.

It is also important to point out that the direction of the ionic strength effect on rate constants does not always correlate with the protein net charge. Thus, in reactions with FMN [47] and flavodoxin [48], three species of cytochrome c_2 having net charges of -7 , 0 and $+2$ all show attractive electrostatic interactions during ET with these negatively charged species. The reason for this behavior lies in the fact

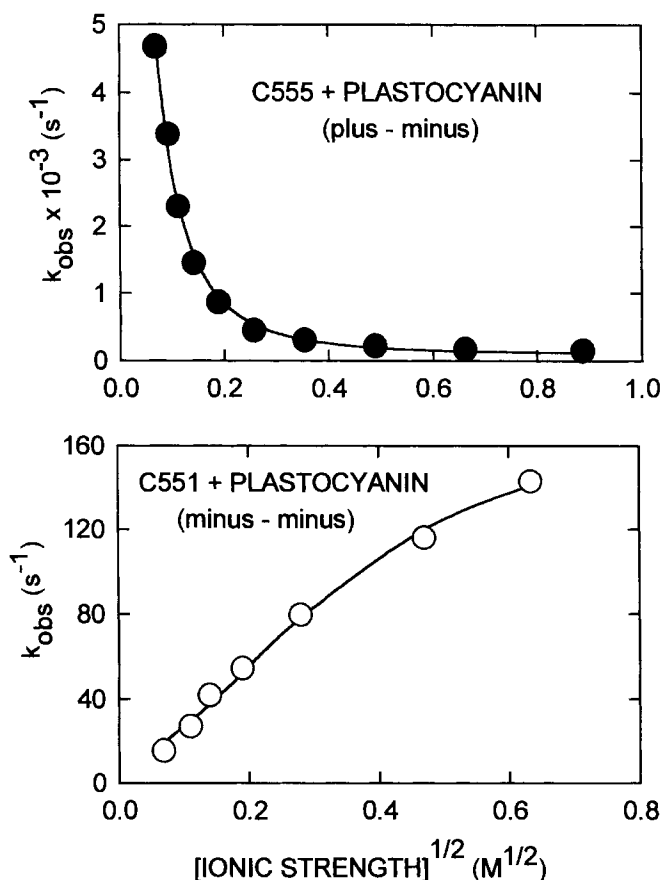

Figure 1. Ionic strength dependence of observed rate constants for ET from two reduced cytochromes (*c*₅₅₅ and *c*₅₅₁) to oxidized plastocyanin. Solid lines are theoretical fits to the data points using the parallel plate model (only the V_{ii} term is included).

that the distribution of acidic and basic residues in each of these cytochromes places a positive charge near the solvent-exposed edge of the heme. Thus, it is the *local* charge near the ET site that dominates the electrostatic interactions. More dramatic deviations from these patterns, obtained with several physiological interprotein reactions, will be described below.

5.3 Interprotein Electron Transfer Reactions

5.3.1 Ferredoxin (Fd)–Ferredoxin:NADP⁺ Reductase (FNR)

FNR is involved in the reductive side of photosynthesis, transferring electrons from reduced Fd to NADP⁺. The enzyme, as isolated from the cyanobacterium

Anabaena, is a 36 kDa basic protein having a noncovalently bound flavin (FAD) cofactor. Fd is a smaller (11 kDa) acidic [2Fe–2S] protein that is present in all photosynthetic organisms, and acts as a shuttle between larger proteins (in this case the iron–sulfur subunit of photosystem I and FNR), which are often anchored in membranes and have restricted mobility. Note that Fd is a one-electron carrier and NADP^+ requires the simultaneous addition of two electrons for its reduction.

Inasmuch as the FAD cofactor is capable of accepting two electrons in one-electron steps, with the intermediate formation of a neutral flavin semiquinone, reduction of NADP^+ proceeds via two Fd–FNR ET reactions. The one-electron reduction potentials for the proteins are as follows [49]. For FNR the values are –331 and –314 mV for the first and second reduction steps, respectively, and for Fd the value is –384 mV. Thus, both ET processes are slightly exoenergetic. Interestingly, complex formation between the two oxidized proteins increases the redox potential difference for the first ET reaction by about 30 mV, thereby increasing the thermodynamic driving force [49].

The 3-D structure of *Anabaena* FNR has been determined to 1.8 Å resolution (Figure 2, top), and shows two separate domains where the cofactor FAD and the substrate NADP^+ bind [50]. Several lines of evidence indicate that Fd binds within a concave surface that occupies both domains of FNR. The exposed dimethylbenzene ring of the flavin protrudes from this surface in a manner that probably allows close interaction (~ 5 Å) between the iron–sulfur center of Fd and the FAD in the enzyme [51, 52]. The 3-D structure of *Anabaena* Fd (Figure 2, bottom) has also been determined to high resolution [53]. The protein contains a large number of conserved acidic amino acid residues on its front surface surrounding the largely buried [2Fe–2S] center. However, the surface regions closest to the [2Fe–2S] center are electrically neutral. Both Fd and FNR from *Anabaena* have been cloned and overexpressed in *E. coli*, allowing site-specific mutagenesis to be applied, hence this system provides an ideal model for investigating protein–protein ET.

Laser flash photolysis time-resolved spectrophotometry, utilizing deazariboflavin–EDTA as a photochemical reductant, has been used with this system in order to characterize the initial step in the ET mechanism. Figure 3 shows examples of the type of data obtained in these studies. In the top panel, a transient is shown [54] that was obtained at 507 nm in 100 mM phosphate buffer, pH 7.0, containing 35 μM Fd, and in the middle panel, 10.3 μM FNR has been added to the solution prior to photolysis. This wavelength corresponds to an isosbestic point for the FAD cofactor of the reductase, and thus the absorbance change monitors the oxidation state of the [2Fe–2S] cluster of Fd (and also the formation and decay of the dRfH^\bullet species). As is evident, immediately after the laser flash there is a rapid rise in absorbance due to dRfH^\bullet formation. This is followed by a sharp absorbance decrease corresponding to Fd reduction and dRfH^\bullet oxidation. The subsequent slow increase in absorption shown in the middle panel is a consequence of Fd reoxidation that is due to electron transfer to FNR. The latter is confirmed by measurement at 610 nm (bottom panel), a wavelength which monitors FAD neutral semiquinone formation; the rate constant obtained from the 610 nm absorbance rise is the same as that obtained from the slow absorbance increase at 507 nm, consistent with this interpretation.

Figure 2. Space-filling models of the front surfaces of *Anabaena* FNR (top) and Fd (bottom). The FAD cofactor in FNR is partially exposed and shown in light shading. The buried iron-sulfur cofactor in Fd is shown in dark shading. For FNR, acidic amino acids are shown in light shading, basic amino acids in dark shading and uncharged amino acids are unshaded. For Fd, basic amino acids are shown in light shading and acidic amino acids in dark shading.

Figure 3. Kinetic transients obtained upon laser flash photolysis of the Fd–FNR system using dRf–EDTA.

Measurement of the FNR concentration dependence of the observed rate constant for reduction of the FAD cofactor yields a hyperbolic curve. After correction for the concentration of the unreactive pre-existing complex between the two oxidized proteins, a non-linear least-squares fit to the data for the two-step mechanism shown in Eq. 7 yields values of $1.7 \mu\text{M}$ for K_D and 5500 s^{-1} for k_{ET} . In comparison, the binding constant between the oxidized forms of the two proteins is $3.3 \mu\text{M}$ under these conditions. Thus, the reduced form of Fd binds more tightly to oxidized FNR than does the oxidized form, which is consistent with the direction of electron flow. The k_{ET} value is not especially large for an ET reaction proceeding over a relatively short distance [17]. Thus, the rate constant probably includes rate limitations imposed by the reorganizational processes accompanying the actual transfer of the electron, e.g., protein structural rearrangements around the active sites and within

Figure 4. Ionic strength dependence of the observed rate constant for electron transfer from reduced Fd to oxidized FNR. The dashed line corresponds to a theoretical fit to the higher ionic strength data using the parallel-plate model. The solid line is a smooth curve drawn through the data points.

the interaction domain, water shell reorganization, etc. This aspect of the reaction mechanism needs further study.

Figure 4 shows the ionic strength dependence of the observed rate constant for ET from reduced Fd to oxidized FNR [26]. Note the biphasic nature of this curve, which is different from what is expected based on a simple electrostatic interaction between the two proteins (corresponding to the dashed curve drawn through the higher ionic strength points; compare with Figure 1). This type of biphasic behavior has also been observed with several other physiological redox protein systems, e.g. cytochrome *c*–cytochrome *c* peroxidase, cytochrome *c*–cytochrome oxidase and cytochrome *f*–plastocyanin (see below), so that it seems to be quite general. The following interpretation of this phenomenon has been given [26]. Both electrostatic and hydrophobic interactions contribute to complex stabilization. The decrease in ET rate constant observed below the optimum ionic strength is due to two effects: formation of a complex between the oxidized proteins that blocks the active site and strong electrostatic effects which force the intermediate ET complex to assume a less productive protein–protein orientation. The latter phenomenon is evident from the fact that the k_{ET} value at the lowest ionic strength ($I = 12 \text{ mM}$) is smaller than that at $I = 100 \text{ mM}$, even after correction for the formation of unreactive complexes between the oxidized proteins. At intermediate ionic strengths, hydrophobic forces become more important and complexes assume their most productive orientations. At ionic strengths above the optimum value, ET rate constants decrease again due to slowing of protein–protein encounters via screening of long-range electrostatic forces by salt ions. The occurrence of these deviant ionic strength effects can be ascribed to the fact that the front surfaces of both Fd and FNR (and also many other ET proteins) contain both charged and non-polar residues, with the charges asym-

Figure 5. Schematic representation of the roles of electrostatic and hydrophobic interactions in the formation of ET complexes between redox proteins. Asymmetric placement of charged residues with respect to the prosthetic groups results in the electrostatically stabilized complex (left) being less optimal for ET than the complex stabilized by interactions between uncharged surfaces (right). This is a consequence of the larger distance between cofactors in the former complex than in the latter.

metrically located relative to the nonpolar regions immediately adjacent to the redox centers (see Figures 2 and 5). This represents an important insight into redox protein interactions.

The effects on the ET reaction of site-specific mutagenesis of surface residues close to the redox centers of both Fd and FNR have provided interesting insights into ET mechanisms [43, 49, 55, 56]. Nonconservative mutations in three positions (shown in Figure 6) in *Anabaena* Fd (S47A, F65A, F65I, E94K, E94Q) dramatically decrease the rate constant for ET from reduced Fd to oxidized FNR (by as much as a factor of 10^4), whereas conservative mutations at these sites (S47T, F65Y, F65W, E94D) result in retention of activity. Mutations of other surface residues in Fd have much smaller effects or none at all. Especially striking is the fact that a charge-reversal mutation at E95, which is spatially very close to E94, has only a minor effect on reactivity. Further, the T48A mutant maintains wild-type reactivity. A similar selectivity was found in the D67, D68, D69 cluster, where a charge-reversal mutation at D68 was found to increase k_{ET} at low ionic strengths, whereas such mutations at the other two positions were inhibitory under these conditions [57]. These results point to a very high level of specificity with regard to surface interactions between the two proteins during ET.

Appropriate experiments have shown that the inhibitory ET effects are not a consequence of changes in protein-protein binding affinity, in Fd redox potential or in the 3-D structures of the mutant proteins [49]. However, nonconservative mutations at the critical positions do have significant effects on a number of protein

Figure 6. Front surface of *Anabaena* Fd showing critical residues for ET (E94, S47, F65), along with closely adjacent residues that have much smaller effects on ET upon mutagenesis (T48, E95). The iron–sulfur cofactor is labeled.

properties besides ET. Thus, in the S47A and E94K mutants, positive shifts of as much as 80 mV are observed in redox potentials, in the absence of any detectable structural changes in the immediate environment of the [2Fe–2S] cluster. Furthermore, protein stability to guanidine denaturation is decreased; this is especially notable in F65 mutants, and can be ascribed to increased solvent exposure of internal hydrophobic surfaces. Additionally, in the S47 and E94 mutants, the chain conformation in the C-terminal region is modified due to disruption of a hydrogen bond network which links the OH group of S47 to the COOH group of E94 and to the OH group of the C-terminal Y98 residue. The present interpretation of these data is that these three positions are critical points in the Fd structure that control the flexibility and/or conformation of a region of the surface which is close to the [2Fe–2S] cluster, and which is crucial for the interaction with FNR. Thus, it would appear that *parallel* effects on redox potential, protein stability and ET reactivity are occurring. In the ET process, it is the relative orientation of the two proteins within an intermediate complex that is being altered by the mutations, indicating that this is a highly sensitive parameter for controlling interprotein ET.

The laser photolysis results on the ET behavior of these mutants have been confirmed by steady-state kinetic measurements [58, 59]. Interestingly, the latter experiments have shown that nonconservative mutations at F65 and E94 not only severely inhibit reactivity with FNR, but also with two other ferredoxin-dependent enzymes, nitrite reductase and nitrate reductase [58]. Apparently, similar structural constraints in their interactions with Fd are also operative in these other enzymes.

Fd mutants have also been constructed in which each of the four Cys ligands to the [2Fe–2S] cluster have been mutated (one at a time) to Ser [60]. Of these, only the C79S mutant has an unstable iron–sulfur center. The other three mutants (i.e., C41S, C46S and C49S) are all reasonably stable, although clearly less so than the

Figure 7. Front surface of *Anabaena* FNR showing residues subjected to mutagenesis. Those residues having the largest effects on Fd binding and ET are shown in dark shading, and those having smaller effects are shown in light shading. The FAD cofactor is labeled.

wild-type protein. They have relatively normal redox potentials (C46S is identical with wild-type FNR, and C49S is shifted by +50 mV), and can react with FNR (although k_{ET} values are smaller than the wild-type protein by factors of 2–3). These results indicate that whereas the cysteine sulfur atoms are not absolutely required for ET, they clearly make important contributions to protein properties, especially to cluster stability.

Mutagenesis of amino acid residues close to the exposed dimethylbenzene ring of the FAD cofactor of FNR has also provided interesting insights into the role of protein structural features in the interaction with Fd [61, 62]. Seven Lys and Arg residues in this region have been individually converted to Glu (Figure 7). The mutant proteins fall into two groups with respect to their ability to undergo ET with Fd. Thus, charge-reversal mutations at K75, R16 and K72 cause the most severe impairment (e.g., the ET rate constant for K75E is decreased by two orders of magnitude), whereas such mutations at K138, R264, K290 and K294 cause a much smaller degree of impairment. The severity of the ET effects clearly correlates with decreased stabilities of complexes between the two oxidized proteins. Those mutated residues that show the largest effects are located in a region of the protein in which positive charge predominates (see Figure 2), and thus charge reversals cause large changes in the local electrostatic surface potential. In contrast, the other residues are located within or close to regions of intense negative electrostatic potential (Figure 2) and therefore the introduction of additional negative charges has a much smaller net effect on the surface potential. Based on these results, it can be concluded that the positively charged region of the FNR surface located in the vicinity of K75, R16 and K72 is especially important in the binding and orientation of Fd during ET. The negatively charged surface located on the other side of the exposed

FAD cofactor may play a repulsive role during binding of the strongly negatively charged Fd, thereby facilitating the achievement of an appropriate orientation of the two molecules for the ET process. The importance of these electrostatic interactions is underscored by the observations that the degree of impairment of these mutations is strongly ionic strength dependent, and that replacement of K75 by Arg results in wild-type ET activity, whereas replacement by Gln or Ser does not [61].

A non-conservative replacement of a Glu residue (E301) close to the exposed portion of the FAD cofactor also results in a strong inhibition of ET with Fd [63]. In this case, it was shown that the carboxyl moiety of this residue was involved in stabilizing the one-electron reduced form of the FAD (i.e. FADH[•]). For both this mutation and the charge-reversal mutants noted above, steady-state experiments [64] support the laser flash photolysis results.

The results obtained thus far strongly support the following view of the Fd–FNR ET process. The opposite net surface charges of the two proteins play an important role in mediating long-range interactions that allow the molecules to approach each other in an orientation that, although not optimal, is approximately correct for ET. During collision, other forces, particularly hydrophobic interactions, become predominant, and align the proteins such that the closest possible distance, and the most effective orientation, between the prosthetic groups is attained. In the Fd–FNR case, this is probably close enough for outer-sphere ET between the [2Fe–2S] cluster and the isoalloxazine ring of the FAD to occur. If the electrostatic forces are too strong, an improper orientation is imposed, whereas if they are too weak, long-range pre-orientation is impaired. This leads to an ionic strength dependence that maximizes at approximately the value believed to exist *in vivo* (i.e., 100–150 mM). This general picture seems to be applicable to a large number of physiological ET protein pairs. However, as is often the case in biology, an all-encompassing generalization is dangerous.

5.3.2 Cytochrome *f* (Cyt *f*)–Plastocyanin (Pc)

The Cyt *f*–Pc redox pair is also involved in photosynthetic ET. Pc plays a role analogous to Fd, in that it serves as an electron acceptor from a membrane-bound complex, cytochrome *b₆f*. The latter mediates electron flow from photosystem II to photosystem I, coupled to proton translocation. Pc is a small, copper-containing protein, consisting of a single polypeptide chain forming an eight-stranded β -barrel. The coordination environment of the high-potential (~ 370 mV) ‘blue’ copper atom consists of two His nitrogen atoms, and sulfur atoms from Cys and Met residues. One of the His ligands (His87) is exposed at the surface in the center of a hydrophobic region. The Cyt *f* component of the complex, which also has a relatively high redox potential (~ 360 mV), is linked to the membrane by a single hydrophobic transmembrane segment, which allows the heme-containing domain to project out of the membrane surface and make contact with the soluble Pc. Note that the ET process is approximately isotopotential. The 3-D structure of the soluble domain of Cyt *f* is known to high resolution [65], as is the structure of Pc [66] (Figure 8). Laser flash photolysis studies (at 5 mM ionic strength) of the proteins isolated from spin-

Figure 8. Front surfaces of Cyt *f* (top) and plastocyanin (bottom). Residues implicated in complex formation between the two proteins are shown in dark shading and are labeled. ach have yielded values of 23 μM for K_D and 2800 s^{-1} for k_{ET} [67]. The latter compares well with the k_{ET} value obtained in vivo [68]. The ionic strength dependence of the in vitro reaction [67], like that of the Fd–FNR reaction, is biphasic with a broad maximum centered at about 40 mM. It is interesting in this context that cytochromes which are not physiological partners of Pc display monophasic ionic strength effects in their reactions with Pc (see Figure 1). This is probably a consequence of a lack of specific regions of complementarity between the charge distributions on these cytochromes and that of Pc. Site-specific mutagenesis [69, 70] has shown that basic residues near the interface between the large and small domains in Cyt *f*, and acidic residues in Pc, are major contributors to the ionic strength dependence (see Figure 8). This implies that the initial interaction domain involves these regions of the two proteins. It is interesting that expression of these Cyt *f* mutations in vivo does not influence the rate of ET, indicating that the diffusion of the proteins to form an intermediate complex is not rate limiting under these conditions [70]. This may be a consequence of the small volume of the chloroplast intermembrane space.

Kinetic measurements [67] and chemical cross-linking studies [71] have indicated that the electrostatic interaction between Cyt *f* and Pc that occurs during the initial collisional encounter does not result in a complex which is optimal for ET, and that internal rearrangement within the collision complex is a necessary component of the reaction mechanism. The structural basis for this has been probed using NMR and molecular dynamics methods [72]. The initial, purely electrostatic, complex has been proposed to consist of an ensemble of relatively ‘loose’ structures which are in rapid equilibrium, and which undergo only slow ET reactions because of the large distances between redox centers that exist in these complexes. The collisional interaction is followed by the formation of a second well-defined, single-orientation complex, stabilized by both electrostatic and other types of forces (hydrogen bonds, hydrophobic interactions, van der Waals contacts). This latter complex is capable of rapid ET, owing to a smaller distance between redox centers. A specific structure for this ET complex has been proposed, in which the redox centers are approximately 11 Å apart, and in which electrostatic interactions occur between those acidic residues in Pc and basic residues in Cyt *f* that have been implicated by the site-specific mutagenesis studies (see Figure 8). In this model, the ET process occurs via the His87 ligand of the Pc Cu atom and the Tyr1 ligand of the heme iron.

5.3.3 Cytochrome *c* (Cyt *c*)–Cytochrome *c* Peroxidase (ccp)

Cytochrome *c* peroxidase, a heme protein isolated from yeast, catalyzes the two-electron reduction of H_2O_2 to H_2O , utilizing two molecules of reduced Cyt *c* as the source of reducing equivalents. In the first step of the catalytic cycle, ccp undergoes a two-electron oxidation by H_2O_2 . This produces an intermediate state in which one oxidizing equivalent is stored in the heme as an oxyferryl ion $[\text{Fe}^{\text{IV}}=\text{O}]^{2+}$, and the second equivalent as a cationic amino acid radical center located on Trp191 (see [16] for an overview). Catalysis is completed by two successive one-electron reductions by reduced Cyt *c*. A large body of evidence (see [73] for details) supports the

Figure 9. Structure of crystalline complex between cytochrome *c* (right) and cytochrome *c* peroxidase (left). The heme cofactors are shown (light shading) as well as two amino acid residues in the peroxidase (dark shading).

idea that two distinct Cyt *c* binding sites, with rather different affinities, exist on ccp. The high affinity site is associated with Trp radical reduction, and corresponds to the 1:1 complex formed between ccp and yeast iso-1 Cyt *c* whose structure has been solved by X-ray crystallography [10]. This structure is shown in Figure 9. Binding of Cyt *c* to the low-affinity site, which is suggested by electrostatic calculations to be located approximately 90° from the high-affinity site (near Asp148; see Figure 9), makes the predominant contribution to oxyferryl heme reduction [73]. In contrast to this proposed mechanism, observations using laser flash photolysis methodology with ruthenium-labelled Cyt *c* at low ionic strength [74] have suggested that two successive intracomplex ET reactions occur, involving transfer from reduced Cyt *c* molecules first to the Trp radical and then to the oxyferryl heme. Experiments with site-specific mutants indicated that both of these reactions occurred in the same region of the ccp molecule, i.e., the high-affinity site. The rate constants for these two reactions using reduced yeast iso-1 Cyt *c* were $2 \times 10^6 \text{ s}^{-1}$ and 5000 s^{-1} , respectively. Trp radical reduction by iso-1 Cyt *c* was shown to be independent of solvent viscosity, whereas a dependence on viscosity was observed for this reaction when horse Cyt *c* was used as the reductant [75]. This was interpreted as indicating that the iso-1 Cyt *c* reaction proceeded via the conformation shown in the crystal structure determination of the complex [10], whereas the slower horse Cyt *c* reaction ($k = 6.1 \times 10^4 \text{ s}^{-1}$) required a prior rearrangement within the complex from a less favorable orientation, as observed in the crystal structure of the horse Cyt *c* complex with ccp [10], to a more favorable iso-1-like orientation. The latter reaction provides another example of conformational control of interprotein ET.

It has also been proposed based on the laser photolysis studies [74] that both the Trp radical and the oxyferryl heme reduction reactions involve an initial ET to the Trp radical. This would require the occurrence of an intermediate step in the two-

reaction sequence that involves intramolecular ET from the reduced Trp radical to the oxyferryl heme in order to regenerate the radical species. Unfortunately, this reaction could not be directly observed in the laser photolysis experiments, and independent evidence exists that this is a very slow process, despite the fact that these two centers are close to one another. Further work appears necessary in order to resolve this matter. However, it is clear that site-specific mutagenesis of Trp191 to Phe strongly inhibits oxyferryl heme reduction [76].

The very large rate constant that is observed for the first step of Trp radical reduction is interesting. In the crystalline complex, the closest edge-to-edge distance between the heme of Cyt *c* and the indole ring of Trp191 is 16 Å. An ET pathway leading from the heme methyl group through ccp residues Ala194, Ala193 and Gly192 was proposed based on the crystallography [10]. Attempts to utilize the structure of the complex, along with estimated values for the reorganization energy (0.4–0.8 eV) and the driving force (0.4–0.5 eV), to calculate k_{ET} for this reaction were made using both Marcus theory and the pathways model [74]. These yielded values that were at least one order of magnitude too low. This points to the difficulties inherent in such calculations for complex protein systems.

5.4 Intraprotein Electron Transfer Reactions

5.4.1 Flavocytochrome b_2 (Fcyt *b*)

This interesting enzyme isolated from yeast is emerging as an important paradigm for intraprotein ET. It functions to catalyze the two-electron oxidation of lactate to pyruvate, utilizing an FMN and a b-type heme as intermediate electron carriers, and Cyt *c* as the terminal electron acceptor. Lactate oxidation occurs at the FMN site to produce the fully reduced flavin, followed by two successive intramolecular one-electron transfers to the heme cofactor, and from there to Cyt *c*. The 3-D structure of the enzyme from *Saccharomyces* [6] shows separate flavin and heme domains connected by a polypeptide bridge (Figure 10). This is a type of structural motif that is commonly found in multicenter redox proteins (see below for other examples), although ‘hard-wired’ connections between redox centers are also found in enzymes such as ascorbate oxidase and cytochrome *c* oxidase. In the Fcyt *b* case, the length of the bridging polypeptide has been shown to play a crucial role in the intraprotein ET reaction, presumably by constraining the relative distance and orientation of the two domains [77]. The propionate groups of the heme extend out of the heme pocket and point towards the FMN, with the closest edge-to-edge distance between the approximately coplanar cofactors being 9.7 Å. A Tyr residue (Y143) from the flavin domain lies between the two cofactors and forms an H-bond to the heme propionate. In the complex of the enzyme with the reaction product pyruvate, Y143 forms an H-bond to the pyruvate carboxylate. Interestingly, pyruvate binding results in stabilization of the FMN semiquinone form [78]. This is a thermodynamic effect achieved by increasing the midpoint potential of the oxidized–semiquinone

Figure 10. Structure of one of the subunits of flavocytochrome b_2 . The heme domain and the heme cofactor are shown on the left and the flavin domain and the FMN cofactor on the right. The connecting polypeptide bridge is shown in dark shading. Also shown is Tyr143 (in light shading), which lies between the two cofactors.

couple, and decreasing the potential of the semiquinone–fully reduced couple [79–81]. In the absence of pyruvate, these one-electron potentials for the native enzyme from *Saccharomyces* have been reported [82] to be -45 and -135 mV, respectively, and the heme potential -3 mV. In the presence of pyruvate, the heme potential is unchanged, the oxidized–semiquinone potential becomes 50 mV and the second potential becomes -125 mV. The structural basis for these effects is unclear at present.

Laser flash photolysis studies using the deazariboflavin system [80, 81] have shown that pyruvate binding also exerts a strong influence on intramolecular ET. In the one-electron reduced enzyme, ET from the FMN semiquinone to the oxidized heme can be observed *only* in the presence of pyruvate; for this reaction, $k_{\text{ET}} = 500 \text{ s}^{-1}$. When the enzyme is completely reduced by stoichiometric addition of lactate prior to laser photolysis with dRf alone, pyruvate binding *inhibits* ET from fully reduced flavin to oxidized heme. This reaction has an observed $k_{\text{ET}} = 2000 \text{ s}^{-1}$ in the absence of pyruvate [81]. Similar values for these two rate constants have been obtained by temperature-jump measurements [82].

A number of observations [6, 83, 84] have indicated that the heme domain of Fcyt b is mobile relative to the flavin domain, and it has been suggested that this conformational mobility may influence the intramolecular ET kinetics [80, 81, 85]. Inasmuch as the pyruvate effects on intramolecular ET do not correlate with the changes in redox potentials, they may provide an example of conformational gating [86, 87]. This remains to be established (see [82] for further discussion). In this context, it is interesting that in the Fcyt b crystal, bound pyruvate apparently acts to increase the mobility of the heme domain to the point where it is no longer visible in the X-ray electron density map [6].

Site-directed mutagenesis clearly demonstrates that changing Tyr143 to Phe strongly decreases the rate constant for flavin semiquinone to heme ET [27, 88]. Redox potential measurements [82] indicate that this mutation shifts the first FMN potential by about 60 mV in the positive direction, and the second potential by about 30 mV in the negative direction, with no change in the heme potential. This is similar to the effect of pyruvate on Fcyt *b* redox potentials, which was still observed in the mutant enzyme. Crystallography [89] indicates that no significant structural changes have occurred in the Y143F mutant, suggesting an important role for the interdomain hydrogen bond. This bond could function either as part of the ET pathway, or as a constraint on the relative positions of the two domains, or both.

5.4.2 Sulfite Oxidase (SO)

SO is found in various vertebrate liver tissues and catalyzes the two-electron oxidation of sulfite to sulfate coupled to the reduction of two molecules of oxidized Cyt *c*. It contains molybdopterin and b-heme cofactors in separate domains connected by a polypeptide bridge, analogous to Fcyt *b*. The smaller N-terminal heme domain resembles cytochrome *b*₅; the C-terminal domain contains Mo(VI) and catalyzes sulfite oxidation coupled to oxo group transfer. Two one-electron intramolecular ET steps, each followed by ET to Cyt *c*, complete the catalytic cycle.

The three-dimensional structure of SO [90] has been solved to 1.9 Å resolution (Figure 11). The distance between the heme and molybdopterin centers in this structure is fairly large (approximately 28 Å between the Mo atom and the edge of the heme ring), and the redox potential difference between the cofactors is small (approximately 10 mV at pH 6 [91]). Despite this, intramolecular ET between the two centers can be fairly rapid; using laser flash photolysis methods, k_{ET} values as large as 2400 s⁻¹ have been observed for the one-electron transfer between the reduced heme and oxidized Mo cofactors [91]. Arguments based on simple Marcus theory predict that k_{ET} should be less than or equal to 100 s⁻¹ for this process. This estimate assumes a coupling-decay constant (β) of approximately 0.9 Å⁻¹ and a zero activation energy. The latter value is improbable inasmuch as the driving force for the reaction is close to zero. Marcus theory predicts a zero barrier only when the reorganizational energy (λ) equals the driving force, and λ is unlikely to be zero in SO. Thus, k_{ET} values much less than 100 s⁻¹ are expected. This discrepancy has led to the suggestion [92] that the flexibility imparted by the long polypeptide tether that connects the two domains allows conformations that bring the heme and Mo centers much closer than shown in the crystal structure. This is supported by the observation [91] that sulfate ion binding at the molybdopterin site acts to inhibit the intramolecular ET reaction, another example of ligand-gated ET involving a reaction product (see above). It is noteworthy that, in the crystal structure, a sulfate anion sits at the bottom of a pocket in the molybdenum domain lined with basic amino acids, and is in contact with an oxygen ligand of the cofactor (Figure 11). This pocket lies on a surface of the molybdenum domain that is approximately 90° from that which is contacted by the heme domain in the crystal structure. Molecular graphics manipulation of the SO structure indicates that the polypeptide tether is

Figure 11. Structure of sulfite oxidase. The heme domain and the heme cofactor are shown on the left and the molybdopterin domain with its cofactor is shown on the right. The connecting polypeptide bridge is shown in dark shading (one residue is not visible in the electron density map). A bound sulfate ion is also shown in dark shading.

long enough to permit the exposed heme cofactor to make contact with this latter region. Furthermore, this region of the heme domain surface is negatively charged, and thus can interact electrostatically with the sulfate-binding pocket in the molybdenum domain. This can nicely account for both the relatively rapid intramolecular ET and the inhibition by sulfate binding. This interesting possibility needs further investigation.

5.4.3 Cytochrome P450BM-3

Cytochromes P450 are a large family of heme-containing monooxygenases that catalyze the hydroxylation of a variety of compounds. They may be either membrane-bound or soluble, and generally utilize either iron-sulfur proteins or flavoproteins as electron donors to the heme. The soluble bacterial fatty acid monooxygenase P450BM-3 is unique in that the flavoprotein reductase moiety, which contains both FAD and FMN cofactors, is fused with the cytochrome moiety within a single 119 kDa polypeptide [93], rather than being located in a separate protein as it is in most other P450 systems. Furthermore, polypeptides containing each of the three co-

Figure 12. Structure of a crystalline complex between the heme (left) and FMN (right) domains of cytochrome P450BM-3. In this complex, the connecting polypeptide bridge (the ends are shown in dark shading) has been severed and a 20-residue segment is not visible in the structure. The heme and the FMN cofactors are shown in dark shading.

factors can be separately expressed [94], indicating the presence of separate domains connected by polypeptide linkers. Mutagenesis has shown that shortening the length of the linker region between the FMN and heme domains by six amino acid residues causes loss of enzymatic activity [95]. Presumably, this does not allow the domains to orient properly with respect to one another [96].

Although the 3-D structure of the holoprotein has not been determined, structures are available for the heme domain [97, 98] and for an FMN-heme construct [99] (the latter is shown in Figure 12). In the two-domain species, the connecting polypeptide bridge (located between residue 458 in the heme domain and residue 479 in the flavin domain) has been proteolytically severed and does not appear in the electron density map [99]. It is not known whether or not this has caused a change in conformation from the native protein. The heme is in a low-spin state, with a cysteine sulfur as the proximal ligand and a weakly bound water molecule on the distal side. The isoalloxazine ring of the FMN cofactor is at an approximately 90° angle to the plane of the heme, at a distance of about 17 Å from the heme edge.

Electron flow within the protein proceeds from the reducing substrate (NADPH) to FAD to FMN to heme. The initial reduction forms fully reduced FAD (FADH₂), which then transfers one-electron to FMN forming the neutral FAD semiquinone (FADH•) and the anionic FMN semiquinone (FMN^{•-}). When the fatty acid substrate is bound within a long hydrophobic channel adjacent to the distal face of the heme, it induces a low-spin to high-spin change and an increase in the heme potential [93]. This probably involves displacement of the water molecule in the sixth coordination position [100] and a decrease in the local dielectric con-

stant. This allows FMN^{•−} to reduce the ferric iron to the ferrous state. The reduction process is coupled to a structural change in the protein, which causes a 6 Å movement of the substrate into a position favorable for hydroxylation [101]. Upon dioxygen binding to the reduced heme iron, a second electron is delivered which generates an oxyferryl intermediate that carries out the hydroxylation reaction.

The redox potentials of the various P450BM-3 cofactors are as follows [99, 102]. For the heme in the absence of substrate, the potential is −370 mV; in the presence of the substrate arachidonic acid, this is raised to −240 mV. The estimated one-electron potentials of the flavins are as follows: FAD (ox/sq) \approx −285 mV; FAD (sq/hq) \approx −380 mV; FMN (ox/sq) \approx −250 mV; and FMN (sq/hq) \approx −150 mV. These values are consistent with electron flow from FAD semiquinone to FMN, and from FMN semiquinone to heme in the presence of bound substrate (ligand-gated ET).

Laser flash photolysis experiments with the FMN–heme domain using the deazariboflavin system [103] have shown that intramolecular ET from FMN semiquinone to heme cannot be observed in the absence of both substrate and CO, the latter serving as a non-redox active substitute for O₂ that binds to the reduced heme. In the presence of saturating amounts of CO (800 μ M), but no substrate, a slow transfer was observed ($k_{ET} \approx 20$ s^{−1}). Although this is against a thermodynamic gradient, trapping of the reduced heme by CO binding may allow this process to proceed. As CO binding is fairly rapid [104], the observed rate constant presumably reflects the ET step. As the substrate (myristic acid in these experiments) concentration was increased, the observed rate constant increased to 250 s^{−1} along a hyperbolic curve with a midpoint at a substrate concentration of 6.8 μ M. The latter value is in satisfactory agreement with the binding constant determined by spectral titration under the same conditions. This suggests that substrate binding is the rate-limiting step in this process, and that the actual value of k_{ET} must be greater than 250 s^{−1}. It was also observed that the rate constant for heme reduction via the FMN semiquinone in the presence of excess substrate increased linearly with increase in CO concentration. It is important that no heme reduction was detectable in the absence of CO, and that the observed rate constant only reached the limiting value of 250 s^{−1} in the presence of saturating concentrations of CO. Again, this indicates that a binding event, in this case one having low affinity and involving CO, is rate-limiting. As the ferric heme does not bind CO, this binding process must somehow convert the protein into a conformational state that enables the ferric iron to accept an electron from FMN^{•−}. Rapid CO binding to the ferrous heme then follows. Although the structural nature of this conversion is unclear, it provides still another example of the gating of intramolecular ET by ligand binding.

5.5 Conclusions

In the examples described above, we have seen that the interprotein ET reactions are controlled mainly by complementary interactions between the surfaces of the

two proteins involved that influence the mutual orientation of the reaction partners. These are mediated both by electrostatic effects between oppositely charged residues, which act at long distances and provide a mechanism whereby recognition and pre-orientation can be achieved prior to actual collision, and by hydrophobic effects, which act at short distances and provide for precise alignment of the prosthetic groups during the ET process. In contrast, the intraprotein ET reactions that have been discussed are strongly modulated by ligand binding effects, which act as gates to control electron flow (for further discussion, see [105]). It is probably significant that the latter systems are enzymes, which utilize much more complex reaction sequences than occur in redox proteins that are mainly designed for pure ET. Because of their domain structural organization, such multicenter enzymes do not require recognition and pre-orientation between individual polypeptides, and therefore control of ET reactions between redox sites must be exercised by other means, usually ligand-binding events. In at least some cases, gating effects are caused by shifts in redox potential upon ligand binding, and thus constitute thermodynamic control mechanisms. In other cases, ligand binding exerts kinetic control. The latter can involve changes in interdomain distance and/or orientation, or steric blockage of electron flow. At present, we know very little about the structural basis for these control processes. This is clearly a fertile area for future study.

6 Novel Organic Syntheses Through Semiconductor Photocatalysis

Horst Kisch and Matthias Hopfner

6.1 Scope and Introduction

Photocatalysis at semiconductor surfaces is a growing field of photochemistry. In addition to its prime importance for the photochemical conversion and storage of solar energy, semiconductor photocatalysis per se is a promising part of general chemistry since it combines photochemistry with electrochemistry and heterogeneous catalysis. Different from homogeneous electron transfer photosensitization by a dissolved molecule, heterogeneous semiconductor photocatalysis opens up the possibility of performing reductive and oxidative reactions simultaneously. This is due to the fact that the light-generated electron–hole pair (e^-/h^+) is transformed into reducing and oxidizing surface centers (e_r^-/h_r^+ , Eq. 1), from which interfacial electron transfer (IFET) with adsorbed substrates (Eq. 2) may successfully compete with recombination (Eq. 3).

Thus, the semiconductor undergoes a double-electron exchange (Eq. 2). In contrast, in the homogeneous case sensitization proceeds via two consecutive one-electron steps (Eqs. 4–6):

In both cases the primary redox intermediates $A^{\cdot-}$ and $D^{\cdot+}$ are transformed into stable products.

The term *photocatalysis* implies that light and a catalyst are necessary to induce or accelerate a chemical transformation [1–9]. This definition includes *photosensitization*, ‘a process by which a photochemical alteration occurs in one molecular entity as a result of initial absorption of radiation by another molecular entity called photosensitizer’ [10], but it excludes the photoacceleration of a stoichiometric thermal reaction, exergonic or endergonic, and irrespective whether it occurs in homogeneous solution [11] or at the surface of an illuminated electrode [12], otherwise any photoreaction would be catalytic. Despite many attempts, there is no general accepted *mechanistic* definition of photocatalysis. It seems more appropriate to use a phenomenological definition by analogy to thermal catalysis. In the latter case a reaction is called *catalytic* when the turnover number, expressed as number of product molecules formed per number of active sites, is >1 [13]. When it is ≤ 1 , the reaction may be termed *assisted*, as commonly done in homogeneous organo-transition metal chemistry [14, 15]. The crucial point, of course, is that the number of active sites of a catalyst powder is usually unknown [16]. Therefore, in almost all cases the differentiation between a catalytic and assisted photoreaction may be impossible. Accordingly, many of the photoreactions conducted in the presence of semiconductor powders and claimed to be ‘photocatalytic’, in reality are semiconductor-assisted photoreactions [17]. An important example is the titanium dioxide-assisted photoreduction of dinitrogen [18]. What is then the difference between *photosensitization* and *photocatalysis*? Essentially there is none, except in a historical sense, since it became common to use the latter term when the sensitizer is a transition metal complex or a semiconductor particle. This usage has the advantage to signal the reader immediately that sensitization involves a complicated multi-step mechanism. In semiconductor photocatalysis the adsorbed substrate can be considered as a surface complex which is expected to change its structure even when light absorption occurs only by the photocatalyst. In addition to this direct effect of light, the original surface may be restructured to a catalytic surface during an induction period, a process well known from thermal heterogeneous catalysis.

Physico-chemical aspects of charge and current generation at semiconductor electrodes in contact with a liquid electrolyte are the classical topic of photoelectrochemistry [19]. They are treated in other parts of this book. Induced by the early observation of Bard et al. that irradiation of titania powder suspended in a liquid solvent promotes electron-transfer reactions of substrates in solution [20–23], a great variety of chemical transformations in the presence of semiconductor powders or colloids have been reported and summarized in recent review articles [24–27]. Some of these reactions are related to prebiotic chemistry, such as the TiO_2 - [18, 28] or CdS-assisted [29] photoreduction of N_2 , the generation of amino acids from CH_4 , N_2 and H_2O in the presence of platinized TiO_2 [30a] and the TiO_2 - or CdS-induced peptide formation from glycine [30b]. The fading of paints [31] and the detoxification of water and air [32] illustrate important technical and environmental aspects of semiconductor photocatalysis. Common to all these chemical processes is that well known products were formed in very low yields and identified spectroscopically rather than isolated. Although high quantum yields were reported in a few cases, it is recalled that quantum yields are measured at short irradiation times and therefore do not give any information on the synthetic usefulness of the

reaction. In general, photocorrosion, the self-destruction of the semiconductor by light-generated charges, often prevents a long-term reaction, indispensable to obtain the products on a preparative scale. In this chapter we shall therefore focus on the question of whether semiconductor photocatalysis at all is a useful alternative synthesis method and whether or not it may open novel pathways for chemical synthesis.

6.2 Heterogeneous Photocatalysis with Semiconductor Powders

6.2.1 Fundamentals

The mechanistic principles which enable a semiconductor powder, suspended in a solution of substrates, to catalyze a photoreaction originate in the field of photoelectrochemistry. For a critical discussion of the basic assumptions made in the deduction of the resulting theories and their relevance to catalysis, the reader is referred to recent review articles [33–35]. The use of a metallized semiconductor particle as a kind of ‘short-circuit’ micro-photoelectrochemical cell was introduced through the work of Kreutler and Bard on the photo-Kolbe reaction [36]. Differences from the macroelectrodes employed in more conventional photoelectrochemistry have been discussed [34, 37–40].

Almost all of the hitherto observed photoreactions can be rationalized by the simplified mechanistic scheme as depicted in Figure 1 for a platinized semiconductor particle. It is noted that platinization in most but not all cases is required in order to obtain acceptable reaction rates.

The light-generated electron–hole pair may undergo primary recombination through radiative and non-radiative pathways (process 1, Figure 1), or may be

Figure 1. Schematic description of the photoredox reaction $A + D = A_{red} + D_{ox}$ catalyzed by a platinized semiconductor, a typical example of semiconductor photocatalysis type A; for secondary back electron transfer, see Eqs. 7 and 8.

trapped at unreactive (e_{tr}^-/h_{tr}^+) or reactive (e_r^-/h_r^+) surface sites (processes 2 and 3, Figure 1). For colloidal TiO_2 irradiated at low laser intensity, where about five electron–hole pairs are generated per particle, hole trapping occurs in a few hundred nanoseconds whereas electron trapping proceeds in the picosecond time regime. Secondary recombination (processes 4 and 5, Figure 1) is rather slow with a lifetime of the electron–hole pair in the range of 2 μs [41]. In competition with the recombination from reactive centers are the IFET processes (processes 6 and 7 in Figure 1) which afford the radical ions $A^{\cdot-}$ and $D^{\cdot+}$. From picosecond laser flash experiments at CdS colloids it was found that the IFET from e_r^- to an adsorbed viologen acceptor is finished within 18 ps whereas the IFET from adsorbed diethyldithiocarbamate to h_r^+ occurs within 200 ps [42]. Since the diameter of the semiconductor particles in most cases is smaller than the space-charge region, not band bending but competition between the two IFET reactions and the secondary recombination (process 5, Figure 1) is responsible for charge separation. This mechanism of charge separation is supported by the oxidation of alcohols at titania powder electrodes [43, 44]. The primary redox products $A^{\cdot-}$ and $D^{\cdot+}$ have to undergo a fast conversion to the final products A_{red} and D_{ox} in order to avoid primary (process 8, Figure 1) and secondary back-electron transfer (Eqs. 7 and 8):

Thus, in general, a reduced and an oxidized product are obtained, in complete analogy with a classical electrochemical reaction. Except for a very few examples, almost all reactions photocatalyzed by semiconductors fall within this scheme and we have proposed to classify such reactions as *semiconductor photocatalysis type A* [45].

It is generally assumed that owing to the short lifetime of the light-generated charges, only adsorbed substrates can undergo an efficient chemical reaction. However, in the case of the titania-photocatalyzed oxidation of benzyl alcohol and of rhodamine B weakly adsorbed substrates react faster than strongly adsorbed substrates [46–48]. However, this does not necessarily imply that the IFET occurs over a large distance, or that an initially formed OH radical oxidizes the substrate in the bulk solution, since the rate of a semiconductor-catalyzed photoreaction depends on many parameters not known in detail (see below). In Figure 2 a simple corresponding energy profile is displayed, illustrating substrate adsorption and product desorption assuming that the IFET is rate determining.

6.2.2 Thermodynamic Aspects

The thermodynamic feasibility of the IFET reactions can be predicted by comparing the redox potentials of e_r^- and h_r^+ with those of the two substrates A and D. Whereas the latter are easily accessible [49], this is not the case for the former. However, their values can be estimated by assuming that they are positioned close

Figure 2. Energy profile of the reaction depicted in Figure 1.

to the edges of conduction and valence band. Figure 3 summarizes band-edge positions of TiO_2 , ZnS and CdS at pH 7 as measured photoelectrochemically. For single crystals in aqueous systems they usually shift cathodically with increase in pH by approximately 0.06 V per pH unit, as reported for ZnS [51], CdS [52] and TiO_2 [53]. In neutral aqueous solution the values for the conduction (E_{cb}) and valence band edges (E_{vb}) of ZnS [51, 54] and CdS [55] single crystals are $-1.84/+1.84$ V and $-0.9/+1.5$ V (vs. NHE), respectively. In addition to this pH dependence, surface impurities, adsorbed compounds and the change to organic solvents may induce strong band shifts. In the case of CdS it has been reported that removal of

Figure 3. Band edge positions of some n-type semiconductors at pH 7. (a) Single crystal; (b) powder.

Figure 4. Influence of semiconductor nature on the chemoselectivity of lactic acid photo-oxidation.

traces of elemental sulfur and cadmium from the surface results in a cathodic shift of 1 V! [56]. Addition of neutral RSH has no influence whereas the charged RS^- shifts the band positions by 0.4 V cathodically [57]. The same shift of 0.4 V is observed when neutral water is replaced by acetonitrile as the solvent [25]. In the case of a TiO_2 powder electrode the latter shift amounts to 1.0 V [58]. Apparent differences in band positions of single crystals and powders are usually due to the presence of surface states in the latter [56]. In general, the IFET is assumed to occur from these surface states.

From the discussion above it follows that for a given semiconductor-photocatalyzed reaction the variation of catalyst preparation, kind of solvent and substrate adsorption may induce a shift of band positions. The estimation of the driving forces for the two IFET reactions is therefore connected with a large uncertainty. However, neglecting possible kinetic barriers, in many cases it rationalizes the observed experimental results. An example is the photo-oxidation of lactic acid. Whereas platinized TiO_2 catalyzes oxidation to acetaldehyde, platinized CdS induces oxidation of only the OH group affording pyruvic acid (Figure 4). This is in accordance with the less oxidizing property of $h\nu^+$ since the valence band edge of CdS is located about 0.5 V more cathodic as compared with TiO_2 [59]. The other possibility for introducing chemoselectivity is to vary the reduction potentials of the substrates but not to change the semiconductor. It was reported that the introduction of two methoxy groups in the *para*-positions of benzophenone shifts the reduction potential to the negative of the conduction band edge of highly pure cadmium sulfide and thus prevents the reduction to alcohols as observed with other aromatic ketones [60].

6.2.3 Kinetic Aspects

Owing to the heterogeneity of the reaction system, kinetic experiments are not as straightforward to conduct and interpret as in homogeneous photochemistry. Especially quantum yield determinations are ambiguous since it is difficult to correct for the amount of light scattered by the photocatalyst powder. Various attempts have been made to overcome these difficulties [61–63] in order to allow comparisons of quantum yields measured by different experimentalists. However, no general agreement has been reached so far.

The following qualitative considerations illustrate the problem of quantitative comparisons. Assuming that the efficiency of formation of the reactive electron-hole pair (η_r), the efficiency of the IFET (η_{ifet}) and the efficiency of product formation from the primary redox products (η_p) are given by the ratio of the rate constants for formation and consumption of the corresponding intermediate (Eqs. 9–11; see Figure 1; k_{sb} denotes the rate constant for the secondary back-electron transfer according to Eqs. 7 and 8), the rate of reaction is obtained according to Eq. 12, where I_a denotes the intensity of absorbed light:

$$\eta_r = \frac{k_3}{k_1 + k_2 + k_3} \quad (9)$$

$$\eta_{\text{ifet}} = \frac{k_{6,7}}{k_5 + k_{6,7}} \quad (10)$$

$$\eta_p = \frac{k_{9,10}}{k_8 + k_{\text{sb}} + k_{9,10}} \quad (11)$$

$$\text{rate} = \Phi_p I_a = \eta_r \eta_{\text{ifet}} \eta_p I_a \quad (12)$$

Accordingly, the quantum yield of product formation, Φ_p , can be formulated as the product $\eta_r \times \eta_{\text{ifet}} \times \eta_p$ and it is difficult to prove which term is decisive. The last term may be relatively independent on small changes of the semiconductor properties, whereas the two other terms may change considerably. Fairly minor alterations during the synthesis of the powder can lead, e.g., to different amounts of adsorbed ions and therefore vary the photophysical properties of the semiconductor-liquid interface. Furthermore, when the quantum yields for various substrates are compared, it is difficult to relate changes to a specific process of the multi-step reaction.

The dependence of quantum yield on the intensity of the absorbed light can be characterized by two limiting cases [64]. At high light intensity [65], the quantum yield increases linearly with the square root of the reciprocal intensity. This dependence is typical for homogeneous and heterogeneous photoreactions where recombination of primary products is predominant. It has been observed for the TiO_2 -catalyzed photooxidation of 2-propanol [66], the TiO_2/Pt -catalyzed photo-Kolbe reaction [67] and the CdS -catalyzed photoisomerization of *cis*-stilbene [68]. At low light intensity the quantum yield becomes independent of I_a and the reaction rate increases linearly with the first power of I_a . This is observed when the above-mentioned reactions [66, 68] are conducted at low light intensities.

From the discussion above, it is obvious that Φ_p may differ considerably upon minor changes in photocatalyst preparation and solution composition. Higher light intensities may increase recombination [69] and photophysical processes such as emission are strongly influenced by adsorbed impurities [70, 71]. It has been reported that increasing grinding times of ZnS powder enhance its photocatalytic activity in the isomerization of olefins [72] through the generation of reactive surface states; once formed, these catalyze the $[2 + 2]$ cycloaddition of phenyl vinyl ether even in the absence of further irradiation [73]. It is therefore not surprising that quantum yields and chemoselectivities reported by one research group may

differ from those obtained by another group. Furthermore, accurate measurement of Φ_p is difficult in these heterogeneous systems [61] owing to problems of light reflection and scattering, which may lower the effective absorbed light intensity by 15–80 % [62].

Increasing the temperature may influence the slowest chemical reaction step and the adsorption equilibria of substrates and products. Depending on the relation of the two latter steps and on the temperature range investigated, the measured activation energy, E_a , may be zero or larger or smaller than zero [74–79]. Since these factors depend on the detailed nature of the photocatalyst, minor modifications may induce variations of E_a . Accordingly, values of 1.7 and 4.2 kcal mol⁻¹ were reported for two different CdS samples used in the photodimerization of *N*-vinylcarbazole [80].

6.2.4 Surface Area and Particle Size

For the influence of the specific surface area of the semiconductor powder on the rate of product formation, two opposite effects are of major importance [81]. One is concerned with the rate of electron–hole recombination which increases linearly with surface area, and accordingly the reaction rate should decrease. The other is a linear increase in the reaction rate of the reactive electron–hole pair with the adsorbed substrates, which should increase product formation. It is therefore expected that, depending on the nature of semiconductor and substrates, the reaction rate, or Φ_p , may be constant, increase or decrease with increasing surface area. This is nicely reflected by the CdS/Pt-catalyzed photoreduction of water by a mixture of sodium sulfide and sulfite. The highest Φ_p values are observed with small surface areas and are constant up to 2 m² g⁻¹. From there a linear decrease to almost zero at a specific surface area of 6 m² g⁻¹ takes place. Upon further increase to 100 m² g⁻¹ this low quantum yield stays constant [82].

In addition to the rate, the chemoselectivity may also depend on the surface area, which is usually determined by the particle size [83]. Especially the possibility of whether one or more electrons are transferred from and to adsorbed substrates may be decided by the particle size as illustrated by the ZnS-catalyzed photo-oxidation of aqueous ethanol [84]. As summarized in Figure 5, only the nanometer-sized ZnS

Figure 5. Influence of semiconductor particle size on the chemoselectivity of ethanol photo-oxidation.

Table 1. Some basic data for charge generation processes in nanometer- and micrometer-sized ZnS [84].

Parameter	Particle diameter	
	3 nm	4 μm
Absorption cross-section at 300 nm/cm ²	5.4×10^{-16}	1.25×10^{-7}
Photon flux/cm ² s ⁻¹	3.4×10^{16}	4.1×10^{17}
e ⁻ /h ⁺ pairs per particle and second, N/s^{-1}	18	5×10^{10}
Time interval $\Delta t = N^{-1}$	54 ms	20 ps

induces the formation of the 1h⁺ oxidation product 2,3-butanediol, whereas the 2h⁺ product acetaldehyde is produced by both photocatalysts.

Owing to the large difference in the absorption cross-sections of the 3 nm and 4 μm particles, the number of electron–hole pairs generated per particle and per second is estimated as 18 and 5×10^{10} , respectively (Table 1). Accordingly, the time interval Δt between the successive absorption of two photons is 54 ms and 20 ps for the nano- and microscale particles, respectively. Hence the chance of the semiconductor exchanging a second electron–hole pair with the substrates should be much greater at the larger particle. In agreement with this reasoning, the intermediate α -hydroxyethyl radical generated at the micrometer particle by the first reactive hole (Eq. 13) is immediately oxidized to acetaldehyde by the second hole (Eq. 14) and has no possibility of dimerizing to 2,3-butanediol or disproportionating to ethanol and acetaldehyde. In sharp contrast, considerable amounts of the diol are produced at the nanometer particle.

6.2.5 Photocorrosion

In 1922, Lenard [85] investigated the unfavorable darkening of the white pigment lithopone, a mixture of zinc sulfide and barium sulfate, that occurred upon prolonged exposition to sunlight. He assumed that the photocorrosion reaction afforded sulfur and metallic zinc. Shortly afterwards it was shown that UV light and the presence of water are necessary to observe this process [86]. Quantitative investigations by Platz and Schenk [87] revealed the additional formation of hydrogen, zinc sulfate and zinc hydroxide. The decomposition of photoexcited ZnS into its elements seems to be a consequence of the quasi-element electronic configuration, 'Zn(0)S(0)', of the lowest lying electron–hole pair [88]. Owing to the highly covalent character of the Zn–S bond, the effective charges of zinc and sulfur can be assumed to be +1 and –1, respectively [88–90]. Since the valence and conduction bands have

sulfur 3p and zinc 4s character, respectively [91, 92], the calculated quasi-element nature of excited ZnS becomes explainable.

The mechanism of photocorrosion seems to be the same for zinc and cadmium sulfide. For the latter it was investigated in detail for colloids [26] and crystals as discussed in the following [56]. In the absence of air, anodic photocorrosion (Eq. 15):

affords elemental sulfur and cadmium ions which are reduced to cadmium metal upon prolonged irradiation (Eq. 16):

This latter reaction competes with the reduction of lattice metal ions (Eq. 17):

In the case of ZnS or metallized CdS powder, the reduction of water is a further competitive process (Eq. 18):

In the presence of air, at short illumination times the overall reaction is

with the cathodic and anodic parts according to Eqs. 20 and 21, respectively:

The anodic process consists of reactions (22)–(25), which are based on detailed comparative photocorrosion studies at single-crystal electrodes and at powder suspensions:

In the first step, lattice sulfide is oxidized to the S^- radical (Eq. 22), which then reduces oxygen according to Eq. 23. The resulting sulfur dioxide radical anion is

finally oxidized to the sulfate ion (Eqs. 24 and 25). Note the surprising feature that oxygen is reduced via a preceding *primary oxidation* step (Eq. 22). The intermediate S^- radical has been detected on ZnS powder by ESR [93, 94] and on colloidal zinc and cadmium sulfide by pulse radiolysis with UV–VIS detection (absorption maximum around 500 nm) [26, 95]. However, the sulfide radical anion can be also formed via the *primary reduction* $S + e^- \rightarrow S^-$ when elemental sulfur is present as an impurity.

At prolonged irradiation times in the presence of oxygen, the reduction of cadmium ions according to Eq. 16 becomes more important and the overall corrosion reaction follows Eq. 26:

All these photocorrosion processes are, of course, undesirable and it is obvious that their relative importance depends strongly on the presence of surface states which may facilitate recombination or redox reactions with adsorbed substrates. It is well known from ESR [69, 70, 94] and emission spectra [94] that most of these metal sulfide powders contain surface states. They are introduced during preparation of the powder as a result of lattice defects [72, 96], trapped holes [94], surface impurities [97] and metallization [38], and during the actual catalytic reaction as a consequence of irradiation and substrate adsorption. The stabilizing effect of platinization is exemplified by Figure 6 for the ZnS-catalyzed reduction of water in the presence of sodium formate [98]. Note that platinum does not accelerate the reaction but doubles the time of constant catalytic activity from 1 to 2 days. Similarly, the apparent product quantum yield of the 2,5-DHF dehydrodimerization is not increased but slightly decreases when platinizes ZnS is the photocatalyst [97].

6.2.6 Characterization of ZnS and CdS

From the results presented above it follows that catalytic activity and chemoselectivity of a semiconductor photocatalyst should depend on intimate details of the preparation method. In addition to careful description of these synthetic details, it is important to characterize the powder obtained by bulk and surface elemental analysis, by determination of crystal structure, specific surface area and surface charge, by ESR and electronic absorption and emission spectroscopy and by photoelectrochemical experiments to prove the semiconducting properties. The latter are of special importance in order to disfavor a general heterogeneous catalysis mechanism which usually does not involve simultaneous reductive and oxidative interfacial electron transfer steps [99, 100]. Their involvement may be demonstrated by the effects of electron and hole scavengers added to the reacting system. In the following we summarize the most important physical properties of the ZnS and CdS powders employed as photocatalysts in the syntheses of novel organic compounds.

Zinc sulfide was prepared from sodium sulfide or thiourea and zinc sulfate. The resulting porous powders contain about 2–3 % [101] water, have specific surface areas in the range 100–170 m² g⁻¹ and consist of 1–10 μm particles which are

Figure 6. Effect of platinization on the ZnS-catalyzed photoreduction of water by sodium formate.

composed of cubic nanocrystals [102]. Elemental analyses of the bulk materials afford the ratio $\text{Zn:S} = 1.00:0.97$, whereas surface analyses reveal values of $\text{Zn:S} = 1.00:1.35$ to $1.00:1.60$. This significant excess of surface sulfur may be responsible for the pronounced photostability of these samples even when irradiated in an aqueous suspension in the absence of any other substrate. In contrast, zinc sulfides which have a surface excess of zinc immediately suffer photocorrosion [97]. Diffuse reflectance spectroscopy indicates a weak sub-bandgap absorption starting at about 400 nm followed by the steep onset of the band-to-band absorption at 360 nm; in some cases a weak absorption maximum is observable at 450 nm, most likely due to the presence of a surface sulfide species [97]. Accordingly, the emission spectrum of the powder contains, in addition to the bandgap emission at about 360 nm, broad bands around 400 and 490 nm which originate from recombination of the electron-hole pair scavenged at shallow and deep traps within the bandgap [97, 103]. Further emissions at 525 and 690 nm are due to traces of zinc oxide; at higher concentrations, ZnO completely inactivates the photocatalyst. Slightly different to the dry powders, the emission spectrum of an aqueous ZnS suspension exhibits, in addition to the band-to-band emission, only one further band at 430 nm. This *self-activated* emission [105, 106] is generated by excess surface zinc ions (sulfur vacancies) as indicated by its disappearance upon addition of sulfide ions [107]. From the difference

from the bandgap energy of 3.6 eV one can estimate that the corresponding surface state is located about 0.7 eV below the conduction band edge, i.e., at a potential of -1.1 V (at pH 7); a value of 1.0 V has been cited for another zinc sulfide sample [84].

Time-resolved emission spectra exhibit multi-exponential decay at 340 and 437 nm corresponding to lifetimes in the range 0.1–10 ns [107]. The longer lifetimes agree with those reported for other ZnS powders [108] and for colloids [26, 94]. It is recalled that multi-exponential decay may originate not only in different emitting states but also in the presence of various particle sizes [109–111].

The n-type character of these zinc sulfides is indicated by the observation of an anodic photocurrent upon illumination of a powder-coated electrode. The action spectrum of the photocurrent parallels the wavelength dependence of the apparent quantum yield of the photoreduction of water by sodium formate, except that hydrogen evolution starts already in the sub-bandgap region at 370 nm, a wavelength where no photocurrent was observable [98].

Cadmium sulfide was prepared from sodium sulfide and an aqueous ammonia solution of cadmium sulfate. Similarly to the zinc sulfides, the powders obtained contain 2–3 % water, have specific surface areas of about $160\text{ m}^2\text{ g}^{-1}$ and consist of nanoscaled micrometer aggregates as illustrated by Figure 7 [112]. An anodic photocurrent is also observable for a CdS/ITO electrode as displayed for various excitation wavelengths in Figure 8. Addition of methanol induces photocurrent doubling with a factor of about two, irrespective of the energy of excitation. From measurement of the flat-band potential according to the slurry method [52, 113], the position of the conduction band edge at pH 7 is found to be at -0.4 V (vs. NHE) [114].

6.3 Semiconductor Photocatalysis Type A

6.3.1 Dealkylation, Cyclization and Hydroalkylation

Stimulated by the early work of Bard et al. on the TiO_2 -catalyzed photo-Kolbe reaction [36], many papers appeared in subsequent years dealing with *photocatalytic* organic reactions [115] in the presence of colloidal or suspended semiconductor particles. They include *cis-trans* isomerizations [68, 93, 116–119], valence isomerizations [120, 121], substitution and cycloaddition reactions [73, 80, 122–125], oxidations [126, 127], and reductions [128–130]. Characteristic of all these reactions is that in almost all cases well known compounds were formed, which were not isolated but only characterized by spectroscopic methods. The nature of the products can be rationalized within the mechanistic scheme of semiconductor photocatalysis type A, which means that at least one reduced and one oxidized compound are

Figure 9. Exhaustive dealkylation of methylene blue photocatalyzed by CdS.

Figure 10. Exhaustive dealkylation: C–N bond cleavage of the of the intermediate radical cation.

obtained (see Figure 1). In most cases it is the oxidative part of the reaction where the organic substrate is involved. This means that the reactivity of the initially formed radical cation determines the kind of products formed finally. Typical reactions of radical cations are deprotonation, bond cleavage and electron transfer [131, 132]. An early example which illustrates two important mechanistic cases is the exhaustive photodealkylation of methylene blue and rhodamine B [133, 134] catalyzed by nonplatinized CdS (Figure 9) [135]. Photoexcitation of CdS is a prerequisite, since no reaction occurs when the dye **1** is absorbing exclusively.

In the primary reductive step, oxygen from air or Fe(III) ions function as electron acceptor. The radical cation $1^{+\bullet}$, generated in the oxidative counterpart, loses a proton, affording the strongly reducing α -amino radical (Figure 10), which injects an electron into the conduction band of CdS. Hydrolysis of the resulting iminium salt leads finally to the secondary amine. Repetition of this multi-step reaction affords the completely demethylated product **2**.

When methylene blue is replaced by rhodamine B, dealkylation occurs also if the dye is the light-absorbing species. In this case the reduction potential of the excited state is negative enough to inject an electron into the conduction band of CdS, followed by IFET to adsorbed oxygen. The remaining rhodamine radical cation is converted to the final product as summarized in Figure 10. This mechanistic case is rare since in general light is absorbed by the semiconductor and the radical cation is generated in the oxidative primary step through IFET from the substrate to the reactive hole (h_r^+). In addition to deprotonation via C–H cleavage, radical cations may be transformed to the corresponding radicals also by C–C, C–Si and other bond cleavages. The intra- or intermolecular consecutive reactions of these radicals usually determine the chemoselectivity of the overall reaction. Examples of *intra-molecular* reactions are the cyclizations of the diaminodicarboxylic acid **3** [136, 137] and the hydrazone **5** [138], both of which proceed via C–N coupling.

The postulated reaction sequences are summarized in Figures 11 and 12. It is

$E = \text{CO}_2\text{H}$

Figure 11. Cyclization of 1,5-diaminopimelic acid: intramolecular C–N bond formation of the intermediate radical cation.

($\text{Ar} = p\text{-R-C}_6\text{H}_4$, $\text{R} = \text{H, Me, OMe, Br}$)

Figure 12. Cyclization of the hydrazone 5: intramolecular C–N bond formation of the radical cation.

assumed that water is reduced in the reductive part of the hydrazone cyclization. Note, that for both reactions two electron–hole pairs are necessary to produce one product molecule of 4 and 6 ($2 e^-/2 h^+$ process).

An example of an *intermolecular* consecutive reaction is the hydroalkylation of olefins [139, 140]. TiO_2 photocatalyzes the reaction of benzyltrimethylsilane

E = CO₂H

Figure 13. Hydroalkylation of maleic acid by benzyltrimethylsilane: C–Si bond cleavage of the intermediate radical cation followed by intermolecular addition of the generated radical to maleic acid.

(7) and maleic acid (8) to the hydroalkylation product 10; dibenzyl- (9) and 1,2-dibenzylsuccinic acid (11) are formed as by-products (Figure 13). It is proposed that in the reductive primary step 8 is reduced to the relatively stable radical anion 8^{•−}. The oxidatively formed radical cation 7^{•+} undergoes a fast C–Si bond cleavage to Me₃Si⁺ and PhCH₂[•]. Addition of the latter to 8 followed by proton-coupled reduction by 8^{•−} or e_r[−] affords 10. In contrast to the cyclizations mentioned above, only one electron–hole pair is required to obtain one molecule of the product 10 (1 e[−]/1 h⁺ process).

Hydrazone cyclization and hydroalkylation [138–140] are rare examples of reactions conducted on a preparative scale, since the products were isolated in milligram amounts and not just identified in solution. As already mentioned in Section 6.2.5, photocorrosion of the semiconductor photocatalyst often prevents its use in preparative chemistry. This is very true also for colloidal semiconductors; although the pseudo-homogeneous nature of their solutions allows one to conduct classical mechanistic investigations, until now they were too labile to be used in preparative chemistry [107, 141, 142]. In contrast to the above-mentioned reactions, in recent years we have isolated novel compounds on a gram-scale employing photostable zinc and cadmium sulfide powders as photocatalysts [97, 107, 143–145]. During this work we found also a new reaction type which was classified as *semiconductor photocatalysis type B* [45]. In contrast to type A reactions, where at least one oxidized and one reduced product is formed, type B reactions afford only one unique product, i.e., the semiconductor catalyzes a photoaddition reaction (see below).

6.3.2 Dehydrodimerization of Cyclic Enol/Allyl Ethers and Olefins

Irradiation of an aqueous 2,5-DHF suspension of ZnS ($E_{\text{bg}} = 3.6$ eV, $\lambda \leq 345$ nm) with UV light affords hydrogen and gram amounts of the hitherto unknown dehy-

Figure 14. ZnS-photocatalyzed dehydrodimerization of 2,5-DHF: C–H bond cleavage followed by dimerization and to a very small extent by disproportionation of the generated radicals.

drodimers **12a–c** in isolated yields of 60 % (Figure 14) [143–145]. No reaction is observed in the absence of water and the initially evolved hydrogen gas contains about 90 % of D_2 when D_2O is employed. Colloidal zinc sulfide does not catalyze the dehydrodimerization [107]. The use of platinized CdS induces the reaction also with visible light, but with a lower rate and poorer yield [144]. The structures and statistical ratio of the three regioisomeric dehydrodimers suggest that the products are formed by dimerization of an intermediate dihydrofuryl radical. Accordingly, generation of this postulated radical through hydrogen abstraction by OH, produced by hydrogen peroxide photolysis in the absence of ZnS, also affords the dehydrodimers. However, in addition, 3-hydroxytetrahydrofuran is formed by addition of OH to the double bond and subsequent H-abstraction from 2,5-DHF. In sharp contrast to this result, no 3-hydroxytetrahydrofuran is detected in the ZnS-catalyzed photoreaction. The formation of the products can be rationalized within the scheme for *semiconductor photocatalysis type A* as depicted in Figure 1. In the reductive reaction step water is reduced to hydrogen (Eq. 27), whereas in the oxidative part 2,5-DHF is oxidized to the dihydrofuryl radical and a proton (Eq. 28):

According to this, although water is reduced, it should not be consumed, since it is reformed as indicated by the sum of the two equations. In fact, even after production of 2–3 L of hydrogen, no water consumption could be measured. Further support stems from the observation that the initially observed D_2 content of 90 % drops to 40 % after evolution of 1 L of hydrogen, whereas the sum of HD and H_2

R = H, CH₃

Figure 15. Dehydrodimers isolated from the ZnS-photocatalyzed reactions of 3,4-DHP, 3-MeDHP and cyclohexene.

increased from 10 to 60 % [145]. From these results it is obvious that the formation of D₂ from D₂O in 'sacrificial' systems for water reduction is a necessary but not sufficient criterion for 'permanent' water cleavage [146].

Since the dehydrodimers **12a–c** were not known previously, this reaction is the first example of the preparation of a novel compound through semiconductor photocatalysis. The analogous products **13** and **14** are obtained from 3,4-dihydropyran (3,4-DHP), 3-methyl-2,3-dihydropyran (3-MeDHP) and cyclohexene in isolated yields of 30–60 % (Eq. 29, Figures 14 and 15) [97]. 1,4-Dioxane is not dehydrodimerized, contrary to in situ-prepared zinc sulfide, which otherwise photocatalyzes the same reactions [147].

To unravel the detailed mechanism, substrate adsorption, quenching, inhibition and kinetic studies were conducted for the ZnS-catalyzed photodehydrodimerization of 2,5-DHF [107, 148]. A plot of the amount of 2,5-DHF adsorbed (n_{eq}) against the residual concentration in solution (c_{eq}) exhibits saturation plateaus at $n_{\text{eq(max)}}$ of 2.8×10^{-3} and $65 \times 10^{-3} \text{ mol g}^{-1}$. The first plateau is due to the formation of a mixed solvent–solute surface monolayer and the second corresponds to multilayer adsorption. Assuming that the formation of the monolayer can be described by competitive adsorption between water and 2,5-DHF, the data can be analyzed according to Hiemenz (Eq. 30) [149]:

$$\frac{c_{\text{eq}}}{n_{\text{eq}}} = \frac{N_{\text{A}}\sigma^{\circ}}{A_{\text{sp}}K} + \frac{N_{\text{A}}\sigma^{\circ}}{A_{\text{sp}}}c_{\text{eq}} \quad (30)$$

A_{sp} and N_{A} denote the specific surface area of the powder and Avogadro's number, respectively, and σ° is the area covered by the molecule in the saturated solvent–

solute surface monolayer. A plot of $c_{\text{eq}}/n_{\text{eq}}$ vs. c_{eq} affords a straight line from which the adsorption constant K and the average area occupied by 2,5-DHF in the surface-solute monolayer are obtained as $170 \pm 30 \text{ L mol}^{-1}$ and 10.2 \AA , respectively. The latter value agrees well with 9.1 \AA as calculated for 2,5-DHF adsorbed *edge-on* to the ZnS surface [150]. From the surface density of zinc sites ($11.4 \times 10^{-6} \text{ mol m}^{-2}$) of cubic zinc sulfide [151a] and the specific surface area ($100\text{--}170 \text{ m}^2 \text{ g}^{-1}$) of the ZnS employed, one can estimate that the surface concentration of 2,5-DHF in the saturated monolayer is in the range $(1\text{--}2) \times 10^{-3} \text{ mol g}^{-1}$ [151b]. This agrees well with the measured value of $n_{\text{eq}(\text{max})}$. The small downfield shift of 1.5 ppm observed for the $\text{C}(\text{sp}^3)$ atoms of adsorbed 2,5-DHF by ^{13}C NMR suggests that the oxygen atom does not interact directly with zinc sites but rather indirectly through hydrogen bonding to coordinated water.

Only a very few studies have dealt with the problem of whether emissive (e_{tr}^- , h_{tr}^+) and reactive (e_{r}^- , h_{r}^+) surface sites are identical or not. As an example it is mentioned that diethylamine, although it is photo-oxidized at ZnS, does not affect the emission properties [108]. In order to clarify this important point for photo-dehydrodimerization, emission quenching and reaction inhibition studies were performed [107]. Addition of zinc or cadmium sulfate slightly increases or does not alter the emission intensity of an aqueous ZnS suspension, respectively; 2,5-DHF has no significant influence. Since, in contrast, both ions strongly inhibit the reaction, one can conclude that the emitting and reacting surface sites are different. A Stern–Volmer plot of the reduced reaction rate as a function of the initial inhibitor concentration affords a straight line only, when the concentration of *adsorbed* ions is employed (Figure 16). From the corresponding slopes, Stern–Volmer constants of 13×10^3 and $50 \times 10^3 \text{ M}^{-1}$ are calculated for Zn^{2+} and Cd^{2+} , respectively [152].

Inhibition by Cd^{2+} proceeds via competitive IFET (Eq. 31):

since even at the very low concentration of $3.9 \times 10^{-6} \text{ mol g}^{-1}$ the formation of elemental cadmium is observable; complete inhibition occurs at $6 \times 10^{-4} \text{ mol g}^{-1}$. This differs significantly from the effect of zinc ions in which case no elemental zinc could be detected, even at a high concentration of 0.8 mol g^{-1} . From this one can conclude that zinc ions either prevent the formation of the reactive electron–hole pair or efficiently promote its radiationless deactivation (Figure 17).

From detailed inhibition studies with various metal ions, it follows that Mn^{2+} , Fe^{2+} and Ni^{2+} accelerate the reaction whereas Cu^{2+} is weakly inhibiting [148]. At a given surface concentration of these ions, the relative reaction rate (v/v^0) increases approximately linearly with the exchange current density of hydrogen evolution at the corresponding metal electrode (Figure 18); there is no simple relation with the reduction potentials of the ions. This is clear experimental evidence that the water reduction at the photoexcited $\text{ZnS-M}_{\text{ad}}^{2+}$ surface occurs at small metal islands generated by photoreduction. Apparently, in the case of zinc the metal concentration is too low to be detected through the usually employed reduction of methylviologen [107].

From these results, the primary events at the ZnS surface can be summarized as

Figure 16. ZnS-photocatalyzed dehydrodimerization of 2,5-DHF: reduced product formation rate (v°/v) as a function of the concentration of *adsorbed* zinc and cadmium ions.

Figure 17. Dehydrodimerization of 2,5-DHF photocatalyzed by ZnS or CdS/Pt: schematic view of the mechanism. The circle represents a micrometer-sized semiconductor particle, wherein the two horizontal lines correspond to the upper and lower edge of the valence and conduction band, respectively.

the photoaddition reaction [164]. The characteristic data as obtained from application of the Hiemenz model are summarized in Table 2. From the ¹³C NMR spectra of 2,5-DHF adsorbed from the gas phase on the dry powders, it is concluded that 2,5-DHF is adsorbed parallel to the surface. In the case of CdS-SiO₂ the data resemble those of unmodified SiO₂ and therefore suggest that adsorption of 2,5-DHF occurs primarily at the silica surface. In agreement with this conclusion, SiO₂ and CdS-SiO₂ afford the same adsorption constant of 30 M⁻¹, which is about 50 % larger than that for CdS (see below).

From the maximum surface concentration of $n_{eq(max)} = 0.4 \times 10^{-3} \text{ mol g}^{-1}$ found for 2,5-DHF and the maximum number of Cd²⁺ surface sites as calculated for cubic CdS [174], $1.54 \times 10^{-3} \text{ mol g}^{-1}$, it is estimated that 2,5-DHF is adsorbed at about every fourth Cd²⁺ center, in agreement with a parallel adsorption; however, the presence also of perpendicular adsorption cannot be excluded. In contrast, when 2,5-DHF is adsorbed on ZnS from aqueous suspension, it occupies each Zn²⁺ site and σ° matches the calculated molecular area [107]. The difference can be rationalized by comparing the polarities of the two sulfides with those of 2,5-DHF and the solvents employed. Since the surface polarity parameter E_T^N of CdS (0.68 ± 0.06) is comparable to the value for methanol ($E_T^N = 0.762$) [175], but is much higher than that of 2,5-DHF ($E_T^N = 0.366$) [176], displacement of MeOH_{ad} by 2,5-DHF should be disfavored. In contrast, the highly polar solvent water ($E_T^N = 1.0$) [175] is displaced almost completely from the less polar ZnS surface ($E_T^N = 0.57$) [148] by the less polar 2,5-DHF. This explanation is corroborated by the data obtained for 2,5-DHF when it is adsorbed on CdS from an aqueous solution. In this case comparison of the maximum surface concentration of $n_{eq(max)} = (2.1 \pm 0.2) \times 10^{-3} \text{ mol g}^{-1}$ with the calculated maximum number of Cd²⁺ surface sites reveals that about every Cd²⁺ center is occupied by 2,5-DHF. The σ° value of $7 \pm 1 \text{ \AA}^2$ matches fairly well the molecular area of 9 \AA^2 [150] calculated for a perpendicular adsorbed molecule. The change to the more polar solvent water permits an almost five-fold higher surface coverage of CdS. For CdS-SiO₂ the maximum surface concentration of 2,5-DHF ($1.6 \times 10^{-3} \text{ mol g}^{-1}$) is about the sum of the values for CdS-A ($0.4 \times 10^{-3} \text{ mol g}^{-1}$) and SiO₂.

The considerations outlined above are substantiated further by the σ° values as obtained from Hiemenz plots. The area covered by a 2,5-DHF molecule in the

Figure 19. ZnS-photocatalyzed dehydrodimerization of 2,5-DHF: dependence of apparent product quantum yield on substrate oxidation potential.

apparent product quantum yield and redox potential when various substrates are compared (Figure 19). On the other hand, a similar estimation for the concerted process (Eq. 32):

reveals that the reaction is exergonic by at least 0.9 eV [160, 161]. Since the driving force of this reaction is the difference between the free enthalpy of C–H bond homolysis and the potential of the hydrogen electrode, the former value should be decisive when comparing apparent quantum yields of various substrates. Figure 20 displays the relation between the apparent quantum yield and calculated bond dissociation energy of the corresponding C–H bond. The expected increase with decreasing bond strength favors the concerted oxidation pathway. The deviation of 3-MeDHP most likely arises from steric hindrance of the radical C–C coupling step by the adjacent methyl group.

Once formed, the dihydrofuryl radicals may undergo a variety of reactions as known from homogeneous chemistry including disproportionation, addition to double bonds, electron transfer and dimerization. Surprisingly, the latter pathway is followed to about 90 % as indicated by the complete material balance [145]. It is therefore likely that C–C coupling occurs between radicals within the water–2,5-DHF surface layer. This is corroborated by the quadratic dependence of the initial

Figure 20. ZnS-photocatalyzed dehydrodimerization of 2,5-DHF: dependence of apparent product quantum yield on the calculated bond dissociation energy of the allylic C-H bond.

rate on the amount of adsorbed 2,5-DHF which is shown in the linearized form in Figure 21. This dependence corresponds to a heterogeneous catalytic dimerization by a modified Langmuir-Hinshelwood mechanism affording easily desorbable products [162]. It further suggests that at early reaction stages the concentration of adsorbed radicals increases linearly with the bulk concentration of 2,5-DHF. The latter relation breaks down as the reaction progresses, since the consumption of 2,5-DHF is faster than its adsorption from solution. Accordingly, the instantaneous rate decreases more strongly with time for lower than for higher starting concentrations and finally becomes diffusion controlled [148]. C-C coupling between radicals adsorbed in the water-2,5-DHF surface layer is further supported by competition experiments with THF. Although the unsaturated ether reacts only 10 times faster than the saturated ether, no THF dehydrodimers or cross-products are detected when THF is present in 10-fold excess over 2,5-DHF. Only at a 500-fold higher concentration are the expected products observed.

In summary, one can conclude that the formation of H_2 and the dehydrodimer occurs via subsequent adsorption of two photons ($2e^-/2h^+$ process). The intermediately adsorbed hydrogen atom and dihydrofuryl radical generated by the first photon must have lifetimes long enough to wait for the arrival of the second photon. This requirement is easily fulfilled since at a micrometer-sized ZnS particle the time interval between two successive photon absorptions can be estimated to be in range of 20 ps, much shorter than the lifetime of radicals and radical cations which

Figure 21. ZnS-photo-catalyzed dehydrodimerization of 2,5-DHF: dependence of square root of reaction rate on concentration of adsorbed 2,5-DHF.

are in the range of at least nanoseconds. However, the question arises of why the C–C homocoupling between two radicals is so highly favored over C–H heterocoupling with an adsorbed hydrogen atom to reform 2,5-DHF [163]. One possibility is that the first electron does not produce an adsorbed hydrogen atom, but is stored at the metallic zinc center and water is subsequently reduced in a two-electron step. Alternatively, the adsorbed hydrogen atom does not undergo coupling to the dihydrofuryl radical because of unknown kinetic barriers. Therefore, it seemed worthwhile to replace water by an organic acceptor which could produce a more stable one-electron reduction intermediate, perhaps capable of undergoing the postulated heterocoupling with the one-electron oxidation intermediate. The following section illustrates that this concept led to the catalysis of photoaddition reactions, classified as *semiconductor photocatalysis type B*.

6.4 Semiconductor Photocatalysis Type B

6.4.1 Linear Addition of Cyclic Enol/Allyl Ethers and Olefins to 1,2-Diazenes

Upon addition of azobenzene to a running ZnS-catalyzed photodehydrodimerization of 2,5-DHF, hydrogen evolution is completely inhibited in favor of formation of the novel allylhydrazine **13c**, a linear addition product of 2,5-DHF to azo-

Figure 22. Synthesis of allyl hydrazines through addition of cyclic allyl/enol ethers and olefins to 1,2-diazenes photocatalyzed by ZnS or CdS.

benzene; small amounts of hydrazobenzene are formed as a by-product [141, 142]. When all the azobenzene is consumed and some excess 2,5-DHF is still present, hydrogen evolution starts again. Replacing ZnS by CdS or silica supported CdS (CdS/SiO₂) [164], allows one to conduct the reaction with visible light; a simple tungsten-halogen lamp can be used instead of the high-pressure mercury lamp. When colloidal CdS [165] is employed in the system 3,4-DHP-1,2-diphenyldiazene-MeOH, no photoaddition but efficient photocorrosion occurs. Figure 22 summarizes the novel allylhydrazines **13a–15f** prepared on a gram scale by this simple route employing methanol as the solvent [141, 142]. Owing to the poor crystallization properties, isolated yields are only in the range 10–40 % whereas HPLC yields are about twice larger. Structural assignments are based on an X-ray structural analysis of **13b** and on standard spectroscopic data. Dynamic NMR spectra of **13b** reveals that rotation around the N–N bond is hindered; the corresponding free activation enthalpy amounts to 14 kcal mol^{−1}.

From a few examples of limited synthetic utility, it is known that the same reaction type may occur in homogeneous solution when either the 1,2-diazene [166–169] or the olefin [170–172] is substituted by electron-withdrawing groups. Some other allylhydrazines have been prepared by more conventional thermal procedures [173].

The photoaddition exhibits a significant solvent dependence. No reaction occurs in dry *n*-hexane or THF, but upon addition of water or methanol the reaction is as fast as in pure methanol.

Substrate adsorption studies as conducted with ZnS in aqueous solution were performed also with CdS, CdS-SiO₂ and SiO₂ in methanol, the solvent employed in

the photoaddition reaction [164]. The characteristic data as obtained from application of the Hiemenz model are summarized in Table 2. From the ¹³C NMR spectra of 2,5-DHF adsorbed from the gas phase on the dry powders, it is concluded that 2,5-DHF is adsorbed parallel to the surface. In the case of CdS-SiO₂ the data resemble those of unmodified SiO₂ and therefore suggest that adsorption of 2,5-DHF occurs primarily at the silica surface. In agreement with this conclusion, SiO₂ and CdS-SiO₂ afford the same adsorption constant of 30 M⁻¹, which is about 50 % larger than that for CdS (see below).

From the maximum surface concentration of $n_{eq(max)} = 0.4 \times 10^{-3}$ mol g⁻¹ found for 2,5-DHF and the maximum number of Cd²⁺ surface sites as calculated for cubic CdS [174], 1.54×10^{-3} mol g⁻¹, it is estimated that 2,5-DHF is adsorbed at about every fourth Cd²⁺ center, in agreement with a parallel adsorption; however, the presence also of perpendicular adsorption cannot be excluded. In contrast, when 2,5-DHF is adsorbed on ZnS from aqueous suspension, it occupies each Zn²⁺ site and σ° matches the calculated molecular area [107]. The difference can be rationalized by comparing the polarities of the two sulfides with those of 2,5-DHF and the solvents employed. Since the surface polarity parameter E_T^N of CdS (0.68 ± 0.06) is comparable to the value for methanol ($E_T^N = 0.762$) [175], but is much higher than that of 2,5-DHF ($E_T^N = 0.366$) [176], displacement of MeOH_{ad} by 2,5-DHF should be disfavored. In contrast, the highly polar solvent water ($E_T^N = 1.0$) [175] is displaced almost completely from the less polar ZnS surface ($E_T^N = 0.57$) [148] by the less polar 2,5-DHF. This explanation is corroborated by the data obtained for 2,5-DHF when it is adsorbed on CdS from an aqueous solution. In this case comparison of the maximum surface concentration of $n_{eq(max)} = (2.1 \pm 0.2) \times 10^{-3}$ mol g⁻¹ with the calculated maximum number of Cd²⁺ surface sites reveals that about every Cd²⁺ center is occupied by 2,5-DHF. The σ° value of $7 \pm 1 \text{\AA}^2$ matches fairly well the molecular area of 9\AA^2 [150] calculated for a perpendicular adsorbed molecule. The change to the more polar solvent water permits an almost five-fold higher surface coverage of CdS. For CdS-SiO₂ the maximum surface concentration of 2,5-DHF (1.6×10^{-3} mol g⁻¹) is about the sum of the values for CdS-A (0.4×10^{-3} mol g⁻¹) and SiO₂.

The considerations outlined above are substantiated further by the σ° values as obtained from Hiemenz plots. The area covered by a 2,5-DHF molecule in the

saturated surface-solute monolayer, is found to be 50 ± 5 , 35 ± 2 and $20 \pm 1 \text{ \AA}^2$ for CdS-A, SiO_2 and CdS– SiO_2 , respectively, and differs not too much from the area of 21 \AA^2 as calculated for an unsolvated molecule adsorbed parallel to the surface [177]. This qualitative agreement with the conclusions drawn from the maximum numbers of metal ion sites as well as the ^{13}C NMR data strongly suggests that 2,5-DHF adsorbs at surface [OH] or [SH] groups via hydrogen bonding.

Inspection of Table 2 reveals that the adsorption constants of 2,5-DHF on SiO_2 and CdS– SiO_2 are equal. This suggests predominant adsorption on the SiO_2 support in the latter case. The better adsorption on CdS– SiO_2 ($K_{\text{ad}} = 30 \pm 1 \text{ M}^{-1}$) than on CdS-A ($K_{\text{ad}} = 18 \pm 2 \text{ M}^{-1}$) is connected with a faster reaction and a higher product ratio of **13c**:**16**, which increases from 0.9 to 2.1. Since the amount of azobenzene adsorbed is the same for both photocatalysts, it is likely that the higher 2,5-DHF surface concentration induced by SiO_2 increases also the amount of 2,5-dihydrofuryl radicals adsorbed at CdS and therefore accelerates C–N coupling with the PhN–NPh radicals.

In comparison with 2,5-DHF, the maximum surface concentration $n_{\text{eq(max)}}$ for azobenzene of about $10^{-5} \text{ mol g}^{-1}$ is two orders of magnitude lower, whereas the adsorption constants are much higher and do not depend on the nature of the adsorbent. Comparison of the σ° values (Table 2) with the area covered by a flat, unsolvated molecule (52 \AA^2) [178] reveals that σ° for CdS, CdS– SiO_2 , and SiO_2 is 52, 85 and 145 times higher, respectively, than expected. It is estimated that in the case of CdS only every 220th Cd^{2+} site interacts with an azobenzene molecule. Depending on the adsorbent, only 0.7–2 % of the surface area is covered, which suggests that the more polar methanol ($\mu = 1.7 \text{ D}$) efficiently competes with the less polar *trans*-azobenzene [179] ($\mu_{\text{trans}} \approx 0 \text{ D}$) for adsorption sites at the relatively polar CdS surface. Together with the independence of the adsorption constant of the nature of the adsorbent, these results suggest that adsorption occurs through interaction with Brønsted acid sites [112, 164]. In this case the independence of the adsorption constant of the adsorbent can be rationalized since according to the literature CdS and SiO_2 have similar $\text{p}K_{\text{S}}$ values (6.1, 9.0 [180] and 6–8 [181], respectively) and the employed photocatalysts CdS or CdS– SiO_2 and SiO_2 have two surface centers of similar pH values [182].

Apparent quantum yields were measured at 366 nm, the wavelength where light absorption by the diazene is minimized. In the system CdS– R^3H –1,2-diphenyldiazene–MeOH, Φ_{app} of allylhydrazine formation increases from 0.02 (2,5-DHF) through 0.03 (cyclohexene) and 0.04 (3,4-DHP) to 0.05 (2,3-DHF). As also observed for the ZnS-catalyzed photodehydrodimerization, there is no simple relation with the oxidation potential of the donor, which is 2.6 V for 2,5-DHF and cyclohexene and 1.9 and 2.0 V for 3,4-DHP and 2,3-DHF, respectively. Although 3,4-DHP as compared with 2,5-DHF is more readily oxidized than 2,5-DHF by 0.7 V, its quantum yield is only twice as large. In contrast to this weak effect, lowering of the reduction potential of the diazene causes a strong increase in the *relative* quantum yield [183] of diazene disappearance. For cyclohexene addition in the series 1,2-bis(*p*-tolyl)diazene, 1,2-diphenyldiazene and 1,2-bis(*p*-chlorophenyl)diazene, E_{red} varies from -0.82 to -0.75 and -0.66 V [184] and Φ_{rel} increases from 0.5 to 1.0 and 5.0, respectively. Thus, although the *p*-chloro derivative is more easily reduced

Figure 23. Linear addition of cyclic ally/enol ethers and olefins to 1,2-diazenes photocatalyzed by ZnS or CdS: schematic view of the mechanism.

than the *p*-methyl derivative by only 0.16 V, the quantum yield is 10 times larger. No photoaddition or reduction is observed in the case of 2,3-diazabicyclo[2.2.1]hept-2-ene. It is known that aliphatic diazenes are much more difficult to reduce than aromatic diazenes [185].

From the discussion at the end of Section 6.3.2 and the experimental results presented above, a simplified reaction scheme can be constructed (Figure 23). Since the presence of the diazene completely inhibits hydrogen evolution and the reaction proceeds only in protic solvents or in the presence of water, it is very likely that the reductive IFET is a proton-coupled reduction of the diazene to a hydrazyl radical (Eq. 33):

Hydrazyl radicals derived from 1,2 diaryl- and 1,2-dialkyldiazenes have been postulated [186] and identified in homogeneous solution by ESR [187]. The observation that the product **15a**, obtained from 1-*tert*-butyl-2-phenyldiazene, consists of only one isomer is in agreement with the expectation that the hydrazyl radical should be more stable when the unpaired electron is localized rather on the PhN than on the *t*BuN group. The oxidative IFET is assumed to proceed as described for the photodehydrodimerization. Heterocoupling of the hydrazyl and allyl radicals affords the allylhydrazine. Thus, formation of the addition product is a $1e^- - 1h^+$ process, whereas the by-products are formed via a $2e^- - 2h^+$ process, irrespective whether the hydrazobenzene derivative is formed by subsequent reduction or disproportionation of the hydrazyl radical (Eqs. 34 and 35):

The energetic relations between band positions and redox potentials are summarized in Figure 24.

Figure 24. Band positions and substrate redox potentials at pH 7. (a) Single crystal; (b) powder as employed in the synthesis of allylhydrazines; (c) see Ref. [160]. RH = 2,5-DHF.

^a Azobenzene disappearance.

Formation of the hydrazobenzene product is strongly favored when platinized zinc or cadmium sulfide is used as the photocatalyst (Table 3). In both cases the rate decreases considerably and hydrazobenzene becomes the major product. It is known that platinum favors multi-electron processes [34].

Model experiments in homogeneous solution support the involvement of the postulated intermediate radicals [142]. Irradiation ($\lambda > 290$ nm) of a dilute solution of benzophenone and 1,2-diphenyldiazene in 3,4-DHP as a reactive solvent affords the addition product **13a** in a yield of 30 % as indicated by HPLC analysis. The yield is negligible when the concentrations of the first two components are increased

or when an unreactive solvent is employed. It is assumed that benzophenone in its excited triplet state abstracts hydrogen from 3,4-DHP [188, 189] producing benzhydryl and dihydropyranyl radicals. The former transfer a hydrogen atom to the diazene [186] to afford the 1,2-diphenylhydrazyl radical, which couples with the latter to form **13a** [189]. Since it is known that hydrazyl radicals do not abstract hydrogen from C–H bonds [186, 190–192], the preference of the coupling reaction becomes understandable. Although in a much smaller yield of 5 %, the addition product **13a** is obtained also when the irradiation is performed in the absence of benzophenone. In this case the triplet π, π^* state of $\text{PhN}=\text{NPh}$ abstracts hydrogen from 3,4-DHP. No reaction except isomerization occurs upon monochromatic irradiation at $\lambda = 405$ nm which affords the triplet n, π^* state [190, 193].

Indirect evidence that intermediate R^3 radicals are involved stems from the formation of two regioisomers when an unsymmetrical olefin is employed, as indicated by the NMR spectrum of **13e**. More direct evidence is obtained upon conducting the reaction in the presence of the radical scavenger diphenylpicrylhydrazyl [194]. In the case of cyclohexene, formation of the corresponding addition product is indicated by MS analysis [142]. The cyclohexenyl radical was postulated also in the electrochemical oxidation of cyclohexene in methanolic solution [195].

The postulated C–N heterocoupling requires diffusion of the two radicals either in the solvent–solute surface layer or in the bulk solution. In both cases one expects that the reaction rate should decrease with increasing solvent viscosity. To achieve the latter, the CdS-SiO_2 -catalyzed photoaddition of 2,5-DHF to azobenzene was conducted at pressures ranging from 0.1 to 120 MPa [164]. Both the formation rates of the addition and reduction products **13c** and **16** ($\text{R}^1 = \text{R}^2 = \text{Ph}$) decrease with increasing pressure and from a plot of $\ln(\text{rate})$ vs. pressure activation volume ΔV^\ddagger are obtained as 17.4 ± 3.4 and 15.8 ± 2.3 $\text{cm}^3 \text{mol}^{-1}$, for **13c** and **16**, respectively (Figure 25).

However, since with increasing pressure the dielectric constant also increases, the observed effects may originate in the change in this property [196–199]. In order to differentiate between these two possibilities, the rates were measured in a series of alcohols for which viscosity and dielectric constant change in an opposite fashion. While the rates again decrease with increasing viscosity, they increase when plotted as function of increasing dielectric constant (Figure 26). This indicates that the rate decrease at higher pressure is a viscosity effect.

It is unlikely that the activation volume is connected with substrate adsorption or product desorption, since high pressure does not significantly affect the adsorption of uncharged substrates [200]. An influence on the interfacial electron transfer steps is also ambiguous since, contrary to homogeneous solution, where the rates of very fast electron transfer reactions can become diffusion controlled [201], no parallel explanation is possible for the heterogeneous case. Usually interfacial collision rates depend on molecular mass but not on diffusion rates [202]. Therefore, the activation volume measured for the formation of **13c** may stem from the diffusion of the intermediate radicals to each other or from the subsequent C–N coupling step itself. The latter case can be excluded since bond formation between neutral organic species in homogeneous solution in general has a negative activation volume [203–206]. The only exception is radical recombination in the termination step of polymerizations

Figure 25. CdS-photo-catalyzed addition of 2,5-DHF to azobenzene: dependence of logarithm of product formation rates on applied pressure.

[207, 208]. These reactions possess ΔV^\ddagger values in the range of 13–25 cm³ mol⁻¹ which are composed of the large and positive contribution of diffusion and the small and negative part of radical C–C coupling. Hence the activation volume found for **13c** most likely originates primarily from diffusion of the intermediate radicals to each other and only to a minor part from C–N coupling and therefore should resemble the activation volume for the viscous flow of methanol. The fact that the latter value of 8 cm³ mol⁻¹ [209] is significantly smaller suggests that the radicals do not diffuse in the bulk homogeneous solution but in a solvent–solute surface layer. This should result in a higher viscosity and consequently the activation volume should become more positive. In accordance with this interpretation are also the small activation energies of 2.8 ± 0.3 kcal mol⁻¹ (**13c**) and 2.5 ± 0.2 kcal mol⁻¹ (**16**).

Since the same activation parameters as for **13c** were also found for the formation of the reduction product **16**, the disproportionation pathway (Eq. 34), which involves radical diffusion, is favored over the secondary reduction step (Eq. 35). However, the latter may be partly involved as suggested by the slightly smaller pressure effect compared with **13c**.

The conclusion that changes in solvent viscosity are responsible for the observed pressure and temperature effects is further corroborated by the same dependence of the product ratio **13c**:**16**. Irrespective whether the viscosity is calculated from the pressure or temperature experiments, a plot of the product ratio vs. viscosity affords two straight lines with slopes that are identical within experimental error (Figure

Figure 26. CdS-photocatalyzed addition of 2,5-DHF to azobenzene: dependence of product formation rates on solvent dielectric constant modified through application of pressure (dashed lines) or by changing the solvent from methanol over ethanol and 1-propanol to 1-butanol (solid lines).

27). When the different alcohols were used to change the viscosity, the product ratio also decreased with increasing viscosity.

6.4.2 Linear Addition of Cyclic Enol/Allyl Ethers and Olefins to Imines

According to the proposed mechanism for this novel photoaddition reaction, other substrates capable of forming radicals upon CdS photoinduced one-electron oxidation or reduction should undergo similar C–C coupling. Replacing the 1,2-diazene by the trisubstituted imine **17** indeed affords the new homoallyl amines **18a–g** in isolated yields of 30–75 % (Figure 28) [210].

The structure of the new compounds is confirmed by single-crystal X-ray analyses of **18a**, **c** and **d**, and by comparative NMR data in the case of the other products. The two expected regioisomers **18f** and **f'** were isolated in the case of 3,4-dihydropyran (Figure 29).

Thus, product formation can be rationalized by assuming that the allylic radical generated in the oxidative IFET as discussed above undergoes C–C heterocoupling

Figure 27. CdS-photo-catalyzed addition of 2,5-DHF to azobenzene: dependence of the product ratio on the viscosity modified by changing the pressure or temperature.

with the α -aminodiphenylmethyl radical produced according to Eq. 36:

In no cases could a product arising from C–N heterocoupling be observed. Thus, in contrast to thermal routes, which usually involve the use of organometallic intermediates [211–213], the reaction is regioselective and much easier to perform.

When a disubstituted imine (**19a–d**) is employed instead of the trisubstituted imine, in addition to the homoallylamine (**20**) also the hydrodimer (**21**) of the imine, i.e., the dimer of the postulated α -aminobenzyl radical, is isolated (Figure 30) [214, 45]. The observation that the hydrodimer is produced only from the disubstituted and not from the trisubstituted imine parallels the electrochemical reduction which affords hydrodimers from aldimines [215] but not from ketimines [215, 216].

Adsorption of **19a** on CdS was measured from methanolic solution. As observed for the adsorption of 2,5-DHF, the adsorption isotherm indicates the presence of mono- and multilayer adsorption. From the former a maximum surface concentration $n_{\text{eq(max)}}$ of $20 \times 10^{-7} \text{ mol g}^{-1}$ can be estimated. At higher concentrations a linear correlation seems to be present. A similar behavior was observed also for the adsorption of chlorophenols on TiO_2 [46]. Application of the Hiemenz model on the methanol–imine surface monolayer leads to an adsorption constant of $4400 \pm 950 \text{ M}^{-1}$ and a σ° value of 4000 \AA^2 . This is far too large, as indicated by comparison with 50 \AA^2 ($14 \times 3.5 \text{ \AA}$) estimated for a flat unsolvated molecule. This

Figure 28. Linear addition of allyl/enol ethers or olefins to *N*-phenylbenzophenone imine photocatalyzed by CdS.

Figure 29. Regioisomers isolated from the CdS-photocatalyzed addition of 3,4-DHP to *N*-phenylbenzophenone imine.

suggests that only 1–2 % of the surface is covered by **19a** in competition with the solvent. The results resemble those obtained for the adsorption of azobenzene (see Table 2). Assuming a size of 8 \AA^2 for methanol, one arrives at the conclusion that methanol is present in a 500-fold excess over the imine in the methanol–imine surface monolayer. It therefore is rational that **19a** does not influence the photocurrent

Figure 30. Linear addition of cyclopentene to disubstituted imines photocatalyzed by CdS.

of a CdS electrode whereas methanol induces current doubling [217]. Although these numbers are only rough estimates, they are not unexpected since methanol should adsorb much more strongly than **1a** on the hydrous CdS surface [218].

Control experiments with **19a** showed that in the absence of olefins hydrodimers were also formed but the reaction rate was reduced by about 90 %. Either the CdS itself (under photocorrosion) or the solvent must be involved in the oxidative step of this reaction. Accordingly, irradiation of CdS in a solution of **19a** in different alcohols transforms the imine at different rates and the corresponding addition products **22a–e** and the hydrodimer **23** are isolated (Figure 31). Except for methanol and 2-propanol, the products are racemic diastereomeric mixtures which are isolated in low yields (5–20 %); they are often mixed with the two-electron reduction product *N*-4-chlorobenzyl-4-chloroaniline. The major product in all reactions is the hydrodimer **23**, obtained in yields of 10 % (MeOH), 28 % (BuOH), 29 % (PrOH), 42 %

Figure 31. Linear addition of alcohols to a disubstituted imine photocatalyzed by CdS.

(EtOH) and 60 % (*i*PrOH). Upon prolonged irradiation the hydrodimer is partially decomposed. Other by-products were also formed but not isolated. The structure of **22** indicates that in all cases the α -CH bond of the alcohol is added to the imine in agreement with the preferred formation of α -hydroxyalkyl radicals from oxidation of the alcohols [219, 220].

The rate of imine disappearance increased from MeOH (relative rate 1.0) to EtOH (2.0), PrOH (2.0) and *i*PrOH (3.3), in agreement with the easier oxidation of these alcohols. BuOH does not follow this correlation since it induces a relative rate of only 1.8, giving rise to the formation of more side products. In the case of *i*PrOH, involvement of the intermediate hydroxyalkyl radical was corroborated through detection of its disproportionation product acetone. These results show that the solvent can be directly involved in the oxidative step. Formation of hydrodimers in the absence of olefins thus can be explained by the oxidation of the alcohols. It is noted that in the presence of olefins no alcohol addition products could be detected by HPLC analysis, although methanol is present in a 500-fold molar excess.

Decreasing the light intensity to 10–50 % of its original value results in a linear decrease in the reaction rate. Above 50 % a saturation effect is observed. This is in accord with other photoreactions catalyzed by semiconductor powders [66, 68].

At higher intensities the rate usually increases proportionally to $I_a^{1/2}$ owing to enhanced charge recombination as reported for the TiO_2 (specific surface area $7 \text{ m}^2 \text{ g}^{-1}$ [66]) catalyzed photo-oxidation of 2-propanol at light intensities above $10^{16} \text{ quanta s}^{-1}$. In the system investigated here this occurs only above intensities of $10^{18} \text{ quanta s}^{-1}$. It is noteworthy that the product ratio **20a:21a** = 0.9 does not depend on light intensity. Assuming that reductive and oxidative reaction steps are coupled, the rates of α -aminobenzyl and cyclopentenyl radical formation should be equal. When the concentrations of these radicals are taken as equal, one arrives at rate laws for the formation of the two products which differ only in the rate constants k_{add} and k_{dim} . Therefore, their ratio should determine also the ratio **20a:21a** [45]. The fact that the latter does not change suggests that these rate constants are independent of light intensity.

As observed for the photoreduction of methyl orange [218] and the oxidative photodimerization of olefins [80] catalyzed by CdS powder, the dependence of rate on CdS concentration increases approximately linearly and reaches a plateau at about 3 g L^{-1} . Surprisingly, in the same concentration range the ratio of addition to hydrodimer product (**20a:21a**) decreases from 2 to about 1. This can be rationalized by considering that the specific rate v_s , which is the measured rate divided by the amount of catalyst employed, decreases with increasing catalyst concentration (Figure 32).

Figure 32. Dependence of specific rate ($10^{-7} \text{ mol g}^{-1} \text{ s}^{-1}$) and product ratio of addition to hydrodimerization on the concentration of CdS.

In the same direction, the surface concentration of the intermediate radicals should decrease although the ratio of α -aminobenzyl to cyclopentenyl radical concentration should not change. Therefore, the product ratio should stay constant. However, a lower concentration of the radicals increases their lifetime, assuming that they undergo only second-order decay reactions. This effect should favor hydrodimerization, which is a $2e^-/2h^+$ process and therefore requires that a second radical pair is generated during the lifetime of the first. Furthermore, one can make the plausible assumption that there is still some weak interaction within a reactive electron-hole pair and therefore the distance between the charges in a pair should be smaller than the distance between neighboring pairs. This means that the radical homocoupling most likely requires a longer diffusion path than heterocoupling. Accordingly, a longer radical lifetime should also allow more efficient diffusion and therefore additionally favor the hydrodimer formation.

6.5 Summary and Outlook

The unique property of the semiconductor-liquid interface to generate reducing and oxidizing surface sites upon absorption of light enables nanoscaled micrometer particles of zinc and cadmium sulfide powders to act as efficient heterogeneous electron transfer photocatalysts for novel organic syntheses. In most cases a reduced and an oxidized product are obtained, in complete analogy with an electrochemical synthesis (semiconductor photocatalysis type A). In a few cases, as observed only recently, the semiconductor catalyzes a linear photoaddition reaction between two unsaturated substrates affording a single product (semiconductor photocatalysis type B), a reaction type not known in classical electrochemistry. In both reaction types the semiconductor action is at least bifunctional. It allows proper assembly of the substrates through adsorption and it catalyzes a double interfacial electron transfer to and from substrates. The latter affords intermediate radicals which finally undergo regioselective C-C and C-N coupling reactions to stable products. The reactions are easy to perform and the heterogeneous sensitizer can be conveniently separated from the products by filtration. Especially the photoaddition reactions are promising examples of a 'green chemistry' since they do not produce waste materials and they can be driven by solar light. It may be expected that this multifunctional nature of the semiconductor powders can be utilized for further novel preparative reactions, especially in the field of solar energy conversion. In a formal way, the overall reaction resembles photosynthesis, where light absorption also generates reducing and oxidizing centers, which finally induce the synthesis of organic matter through C-C coupling reactions.

Part 2

Heterogeneous Systems

1 Electron Transfer at Semiconductor–Electrolyte Interfaces

Krishnan Rajeshwar

1.1 Introduction and Scope

The study of electron transfer across semiconductor–electrolyte interfaces has both fundamental and practical incentives. These interfaces have interesting similarities and differences with their semiconductor–metal and metal–electrolyte counterparts. Thus approaches to garnering a fundamental understanding of charge transfer across these interfaces have stemmed from both electrochemistry and solid-state physics perspectives and have proven to be equally fruitful. On the other hand, this knowledge base in turn impacts many technologies, including microelectronics, environmental remediation, sensors, solar cells and energy storage. Some of these are discussed elsewhere in this series of volumes.

Nonetheless, it is instructive first to examine the historical evolution of this field. Early work in the 1950s and 1960s undoubtedly was motivated by application possibilities in electronics and came on the heels of discovery of the first transistor. Electron transfer theories were also rapidly evolving during this period, starting from homogeneous systems to heterogeneous metal–electrolyte interfaces leading, in turn, to semiconductor–electrolyte junctions. The 1973 oil embargo and the ensuing energy crisis caused a dramatic spurt in studies on semiconductor–electrolyte interfaces once the energy conversion possibilities of the latter were realized. Subsequent progress at both fundamental and applied levels in the late 1980s and 1990s was more gradual and sustained. Much of this later research has been spurred by technological applicability in environmental remediation scenarios. Very recently, however, renewed interest in clean energy sources that are non-fossil in origin has provided new impetus to the study of semiconductor–electrolyte interfaces. As we also learn to understand and manipulate these interfaces at an increasingly finer (atomic) level, new microelectronics application possibilities may emerge, thus completing the cycle that first began in the 1950s!

The ensuing discussion of the progress that has been made in this field mainly hinges on studies that have appeared since 1990 or thereabouts. Several review

articles and book chapters have appeared since then dealing with semiconductor–electrolyte interfaces [1–10]; aspects related to electron transfer are featured in several of these. This author is also aware of at least three books/monographs/proceedings volumes that have appeared since 1990 [11–13]. The reader would be well advised, however, to consult the many authoritative accounts that exist prior to this timeframe for a thorough coverage of details on semiconductor–electrolyte interfaces in general. Entry to this early literature may be found in the references cited above. In some instances, however, the discussion that follows necessarily delves into research dating back to the 1970s and 1980s.

To facilitate a self-contained description, we will start with well-established aspects related to the semiconductor energy band model and the electrostatics at semiconductor–electrolyte interfaces in the ‘dark’. We shall then examine the processes of light absorption, electron–hole generation and charge separation at these interfaces. Finally, the steady-state and dynamic (i.e., transient or periodic) aspects of charge transfer will be considered. Nanocrystalline semiconductor films and size quantization are briefly discussed, as are issues related to electron transfer across chemically modified semiconductor–electrolyte interfaces.

Dye sensitization of semiconductor surfaces is not considered here, nor are issues related to semiconductor particles, photocatalysis and photoelectrolysis *per se*. These companion topics may be found elsewhere in Volumes I, IV and V. The discussion is phenomenological and is designed to provide an intuitive grasp of the key issues rather than detailed derivations that would have been prohibitive in terms of space constraints in any case. Indeed, the available theoretical framework is only examined in terms of how and with what confidence the pertinent conclusions can be experimentally verified with semiconductor electrodes.

1.2 Electron Energy Levels in Semiconductors and Energy Band Model

Unlike in molecular systems, the energy levels are so dense that they form, instead of discrete molecular orbital energy levels, broad energy bands. Consider a solid composed of N atoms. Its frontier band will have $2N$ energy eigenstates each with an occupancy of two electrons of paired spin. Thus, a solid having atoms with odd number of valence electrons (e.g., Al with [Ne] $3s^23p^1$) will have a partially occupied frontier band in which the electrons are delocalized. On the other hand, for a solid with an even number of valence electrons (e.g., Si having an electron configuration of [Ne] $3s^22p^2$) will have a fully occupied frontier band (termed a valence band, VB). The situation for Si is schematized in Figure 1.

As Figure 2 illustrates, the distinction between semiconductors and insulators is rather arbitrary and resides with the magnitude of the energy band-gap (E_g) between the filled and vacant bands. Semiconductors typically have E_g in the 1–4 eV range (Table 1). The vacant frontier band is termed a conduction band, CB (Figure 2). We shall see later that E_g has an important bearing on the optical response of a semiconductor.

Figure 1. Schematic illustration of how energy bands in semiconductors evolve from discrete atomic states for the specific example of silicon.

Figure 2. Relative disposition of the conduction band (CB) and valence band (VB) for a semiconductor (a) and an insulator (b). E_g is the optical band-gap energy.

For high-density electron ensembles such as valence electrons in metals, Fermi statistics are applicable. In a thermodynamic sense, the Fermi level, E_F (defined at 0 K as the energy at which the probability of finding an electron is 0.5) can be regarded as the electrochemical potential of the electron in a particular phase (in this

Table 1. Some elemental and compound semiconductors for photoelectrochemical applications.

Semiconductor	Conductivity type(s)	Optical band-gap energy eV ^a
Si	n, p	1.11
GaAs	n, p	1.42
GaP	n, p	2.26
InP	n, p	1.35
CdS	n	2.42
CdSe	n	1.70
CdTe	n, p	1.50
TiO ₂	n	3.00 (rutile) 3.2 (anatase)
ZnO	n	3.35

^aThe values quoted are for the bulk semiconductor. The gap energies increase in the size quantization regime (see Section 1.8).

case, a solid). Thus, all electronic energy levels below E_F are occupied and those above E_F are likely to be empty.

Electrons in semiconductors may be regarded as low-density particle ensembles such that their occupancy in the valence and conduction bands may be approximated by the Boltzmann function [14, 15]:

$$n_e \approx N_0 \exp\left(-\frac{E_0 - E_F}{kT}\right) \quad (1)$$

Now we come to another important distinction between metals and semiconductors in that two types of electronic carriers are possible in the latter. Consider the thermal excitation of an electron from VB to CB. This gives rise to a free electron in the CB and a vacancy or hole in the VB. A localized chemical picture for the case of Si shows that the hole may be regarded as a missing electron in a chemical bond (Figure 3). There is a crude chemical analogy here with the dissociation of a solvent such as water into H_3O^+ and OH^- . In either case, equal numbers of oppositely charged species are produced. Thus, Eq. 1 becomes

$$n_i \approx N_c \exp\left(-\frac{E_F - E_c}{kT}\right) \quad (2)$$

$$p_i \approx N_v \exp\left(-\frac{E_v - E_F}{kT}\right) \quad (3)$$

where N_c and N_v are the effective density of states (in cm^{-3}) at the lower edge and top edge of CB and VB, respectively. These expressions can be combined with the recognition that $n_i = p_i$ to yield

Figure 3. A localized picture of electron–hole pair generation (see also Figure 2a) in silicon.

$$\begin{aligned}
 n_i^2 &\approx N_0 \exp\left(-\frac{E_c - E_v}{kT}\right) \\
 &\approx N_0 \exp\left(-\frac{E_g}{kT}\right)
 \end{aligned} \tag{4}$$

To obtain a numerical feel of the situation, N_c and N_v are typically both $\sim 10^{19} \text{ cm}^{-3}$ so that the constant N_0 ($N_c N_v$) in Eq. 1 is about 10^{38} cm^{-3} . For a semiconductor such as Si (with $E_g = 1.11 \text{ eV}$, Table 1), n_i will be about 10^{10} cm^{-3} at 300 K according to Eq. 4. This rough calculation lends credence to the original rationale for the use of Boltzmann statistics for the electron energy distribution in semiconductors (see above).

The above case refers to the semiconductor in its intrinsic state with very low carrier concentrations under ambient conditions. The Fermi level, E_F , in this case lies approximately in the middle of the energy band-gap (Figure 4a). This simply reflects the fact that the probability of electron occupancy is very high in VB and very low in CB and does not imply an occupiable energy level at E_F itself.

In extrinsic semiconductors the carrier concentrations are perturbed such that $n \neq p$. Again, the analogy with the addition of an acid or base to water is instructive here. Consider the case when donor impurities are added to a neutral semiconductor. Since the intrinsic carrier concentrations are so low (sub-parts per trillion), even additions at parts per billion levels can have a profound electrical effect. This process is known as doping of the semiconductor. In this particular case, the Fermi level will shift toward the CB edge (Figure 4b). When the donor level is within a few kT in energy from the CB edge, appreciable electron concentrations are generated by the donor ionization process (at ambient temperatures) such that now $n \gg p$. This is termed n-type doping and the resultant (extrinsic) semiconductor is termed n-type. By analogy, p-type semiconductors have $p \gg n$. The terms minority and majority carriers now become appropriate in these cases. For a p-doped semiconductor case, the Fermi level now lies close to the VB edge (Figure 4c). The move-

Figure 4. Relative disposition of the Fermi level (E_F) for an intrinsic semiconductor (a), for an n-type semiconductor (b) and for a p-type semiconductor (c).

ment of E_F with dopant concentration can also be rationalized via the Nernst formalism [6].

Doping can be done by adding altrivalent impurities to the intrinsic semiconductor. For example, P (a Group 15 or VA element) will act as a donor in Si (a Group 14 or IVA element). This can be rationalized on chemical terms by noting that P needs only four valence electrons for tetrahedral bonding (as in the Si lattice) —the fifth electron is available for donation by each P atom. The donor density,

N_D , nominally is $\sim 10^{17} \text{ cm}^{-3}$. Thus, assuming that $n \approx N_D$ (complete ionization at 300 K), p will be only $\sim 10^3 \text{ cm}^{-3}$ [recall that the product $n_i p_i$ is $\sim 10^{20} \text{ cm}^{-6}$ (see above)], bearing out the earlier qualitative assertion that $n \gg p$.

Impurity addition, however, is not the only doping mechanism. Nonstoichiometry in compound semiconductors such as CdTe (Table 1) also gives rise to n- or p-type behavior depending on whether Cd or Te is in slight excess, respectively. The defect chemistry in these solid chalcogenides controls their conductivity and doping in a complex manner, a discussion of which is beyond the scope of this chapter. Excellent treatises are available on this topic and on the solid-state chemistry of semiconductors in general [16–22].

The foregoing discussion strictly refers to semiconductors in single-crystal form. Amorphous and polycrystalline counterparts present other complications caused by the presence of defects, trap states, grain boundaries and the like. For this reason, we orient the subsequent discussion mainly toward single crystals, although comparisons with the less ideal cases are made where appropriate. The distinction between metal and semiconductor electrodes also becomes important when we consider the electrostatics across the corresponding solid–liquid interfaces; this is done next.

1.3 The Semiconductor–Electrolyte Interface at Equilibrium

1.3.1 The Equilibration Process

The electrochemical potential of electrons in a redox electrolyte is given by the Nernst expression:

$$E_{\text{redox}} = E_{\text{redox}}^{\circ} + \frac{RT}{nF} \ln \left(\frac{c_{\text{ox}}}{c_{\text{red}}} \right) \quad (5)$$

where c_{ox} and c_{red} are the concentrations (roughly activities) of the oxidized and reduced species respectively in the redox couple. The parameter ($E_{\text{redox}} = \tilde{\mu}_{e, \text{redox}}$) as defined by Eq. 5 can be identified with the Fermi level, $E_{F, \text{redox}}$, in the electrolyte. This was the topic of debate some years back [23], although this premise now appears to be well founded. The task now is to relate the electron energy levels in the solid and liquid phases on a common basis.

The semiconductor solid-state physics community has adopted the electron energy in vacuum as a reference whereas electrochemists have traditionally used the standard hydrogen electrode (SHE) scale. Although estimates vary [23–25], SHE appears to lie at -4.5 eV with respect to the vacuum level. We are now in a position to relate the redox potential, E_{redox} (as defined with reference to SHE), with the Fermi level, $E_{F, \text{redox}}$, expressed versus the vacuum reference (Figure 5a):

$$E_{F, \text{redox}} = -4.5 \text{ eV} - e_0 E_{\text{redox}} \quad (6)$$

Figure 5. (a) Energy levels in a semiconductor (left-hand side) and a redox electrolyte (right-hand side) shown on a common vacuum reference scale. χ and ϕ are the semiconductor electron affinity and work function, respectively. (b) The semiconductor–electrolyte interface before (left) and after (right) equilibration (i.e., contact of the two phases) shown for an n-type semiconductor. (c) As in (b) but for a p-type semiconductor.

When a semiconductor is immersed in this redox electrolyte, the electrochemical potential (Fermi level) is disparate across the interface. Equilibration of this interface thus necessitates the flow of charge from one phase to the other and a ‘band-bending’ ensues within the semiconductor phase. The situation before and after contact of the two phases is illustrated in Figure 5b and c for an n-type and p-type

semiconductor, respectively. The net result of equilibration is that $E_F = E_{F,\text{redox}}$ and a ‘built-in’ voltage, V_{sc} , develops within the semiconductor phase as illustrated in the right-hand frames of Figure 5b and c.

It is instructive to examine this equilibration process further. Consider again an n-type semiconductor for illustrative purposes (Figure 5b). The electronic charge needed for Fermi level equilibration in the semiconductor phase originates from the donor impurities (rather than from bonding electrons in the semiconductor lattice). Thus, the depletion layer that arises as a consequence within the semiconductor contains positive charges from these ionized donors. The Fermi level in the semiconductor ($E_{F,n}$) moves ‘down’ and, of course, the process stops when the Fermi level is the same on either side of the interface. The substantial difference in the density of states on either side dictates that $E_{F,n}$ moves farther than the corresponding level, $E_{F,\text{redox}}$, in the electrolyte. A particularly lucid account of this initial charge transfer is contained in Ref. [6].

The band-bending phenomenon, shown in Figure 5b and c, is by no means unique to the semiconductor–electrolyte interface. Analogous electrostatic adjustments occur whenever two *dissimilar* phases are in contact (e.g., semiconductor–gas, semiconductor–metal). An important point of distinction from the corresponding metal case now becomes apparent. For a metal, the charge, and thus the associated potential drop, are concentrated at the surface penetrating at most a few ångströms into the interior. Stated differently, the high electronic conductivity of a metal cannot support an electric field within it. Thus, when a metal electrode comes into contact with an electrolyte, almost all the potential drop at the interface occurs within the Helmholtz region in the electrolyte phase. On the other hand, the interfacial potential drop across a semiconductor–electrolyte junction (see below) is partitioned both as V_{sc} and as V_H leading to a simple equivalent circuit model comprising of two capacitors (C_{sc} and C_H) in series (Figure 6). More refinements of the equivalent circuit description are given later but the point to note now is the rather variant behavior of a metal and a semiconductor at equilibrium with a redox electrolyte.

1.3.2 The Depletion Layer

There is a characteristic region within the semiconductor within which the charge would have been removed by the equilibration process. Beyond this boundary, the ionized donors (for an n-type semiconductor) have their compensating charge (electrons) and the semiconductor as a whole is electrically neutral. This layer is the space-charge region or the depletion layer, so termed because the layer is depleted of the majority carriers. The potential distribution in this interfacial region can be quantified by relating the charge density and the electric field strength as embodied by the Poisson equation [14, 26]. Under restrictive conditions, more fully discussed in Refs. [6] and [14], we obtain a particularly simple expression:

$$V(x) = -\left(\frac{e_0 N_D}{2\epsilon_s}\right)x^2 \quad (0 \leq x \leq W) \quad (7)$$

Figure 6. Electrostatics at a semiconductor–electrolyte interface. A very simplified equivalent circuit for the interface at equilibrium is shown at the bottom. The Gouy layer is neglected in the latter case (see text).

where e_0 is the electronic charge and ϵ_s is the static dielectric constant of the semiconductor. The potential distribution is mapped in Figure 6. We are now in a position to quantify the parameter V_{sc} :

$$V_{sc} = -\left(\frac{e_0 N_D}{2\epsilon_s}\right) W^2 \quad (8)$$

where W is the depletion layer width.

Further reflection shows how the magnitude of W should depend on the semiconductor parameter, N_D . Consider two cases of a semiconductor, one lightly doped (say $N_D \approx 10^{16} \text{ cm}^{-3}$) and another heavily doped ($N_D \approx 10^{18} \text{ cm}^{-3}$). Obviously in the former case, the charge needed for Fermi level equilibration has to come from deeper into the solid and so the magnitude W will be larger. This suggests a strategy for chemical control of the electrostatics at the semiconductor–electrolyte interface [6]. Nominal dimensions of W are in the 10–1000 nm range. This may be compared with the corresponding Helmholtz layer width, typically 0.4–0.6 nm. With the capacitor-in-series model (see above), we can see that the

semiconductor space-charge layer is usually the determinant factor in the total capacity of the interface. Once again, the contrast with the corresponding metal–electrolyte interface is striking. Only when the semiconductor is degenerately doped (leading to fairly large Q_{sc} and ‘thin’ depletion layer widths) or when its surface is in accumulation does the situation become akin to the latter (see below).

1.3.3 Mapping of the Semiconductor Band-edge Positions Relative to Solution Redox Levels

Considerations of interfacial electron transfer require knowledge of the relative positions of the participating energy levels in the two phases. Models for redox energy levels in solution are exhaustively treated elsewhere in this series of volumes. Besides the Fermi level of the redox system (Eq. 6), the thermal fluctuation model [27, 28] leads to a Gaussian distribution of the energy levels for the occupied (reduced species) and the empty (oxidized species) states, respectively, as illustrated in Figure 5a. The distribution functions for the states are given by

$$D_{ox} = \exp \left[-\frac{(E - E_{F, redox} - \lambda)^2}{4kT\lambda} \right] \quad (9a)$$

$$D_{red} = \exp \left[-\frac{(E - E_{F, redox} + \lambda)^2}{4kT\lambda} \right] \quad (9b)$$

where λ is the solvent reorganization energy.

Now consider the relative disposition of these solution energy levels with respect to the semiconductor band-edge positions at the interface. The total potential difference across this interface (Figure 6) is given by

$$V_t = V_{sc} + V_H + V_G \quad (10)$$

where V_t is the potential as measured between an ohmic contact on the rear surface of the semiconductor electrode and the reference electrode (Figure 6). The problematic factors in placing the semiconductor and solution energy levels on a common basis involve V_H and V_G . In other words, theoretical predictions of the magnitude of V_{sc} (and how it changes as the redox couple is varied) are hampered by the lack of knowledge of the magnitudes of V_H and V_G . A degree of simplification is afforded by employing relatively concentrated electrolytes such that V_G can be ignored.

As with metals, the Helmholtz layer is developed by adsorption of ions or molecules on the semiconductor surface, by oriented dipoles or, especially in the case of oxides, by the formation of surface bonds between the solid surface and species in solution. Recourse to band-edge placement can be sought through differential capacitance measurements on the semiconductor–redox electrolyte interface [29].

In the simplest case, as more fully discussed elsewhere [14, 15, 29], one obtains the Mott–Schottky relation (for the specific instance of an n-type semiconductor)

again by invoking the Poisson equation:

$$1/C_{\text{sc}}^2 = \frac{2}{N_{\text{D}}e_0\epsilon_s} \left[(V - V_{\text{fb}}) - \frac{kT}{e_0} \right] \quad (11)$$

where V_{fb} is the so-called flat-band potential, i.e., the applied potential (V) at which the semiconductor energy bands are ‘flat’ leading up to the solution junction. Several points with respect to the applicability of Eq. 11 must be noted.

The Mott–Schottky regime spans about ~ 1 V in applied bias potential for most semiconductor–electrolyte interfaces (i.e., in the region of depletion layer formation of the semiconductor space-charge layer, see above) [15]. The simple case considered here involves no mediator trap states or surface states at the interface such that the equivalent circuit of the interface essentially collapses to its most rudimentary form of C_{sc} in series with the bulk resistance of the semiconductor. Further, in all the discussions above, it is reiterated that the redox electrolyte is sufficiently concentrated that the potential drop across the Gouy layer can be neglected. Specific adsorption and other processes at the semiconductor–electrolyte interface will influence V_{fb} ; these are discussed elsewhere [29, 30], as are anomalies related to the measurement process itself [31]. Figure 7 contains representative Mott–Schottky

Figure 7. Mott–Schottky plots for n- and p-type GaAs electrodes in an AlCl_3 –*n*-butylpyridinium chloride molten-salt electrolyte. (Reproduced with permission from Ref. [32].)

plots for both n- and p-type GaAs electrodes in an ambient temperature molten salt electrolyte [32].

Once V_{fb} is known (from measurements), the Fermi level of the semiconductor at the surface is defined. It is then a simple matter to place the energies corresponding to the conduction and valence bands at the surface (E_{CB} and E_{VB} , respectively) if the relevant doping levels are known. The difference between E_{CB} and E_{VB} should roughly correspond to the semiconductor band-gap energy, E_g (see Figures 4 and 7). Alternatively, if V_{fb} is measured for one given state of doping of the semiconductor (n- or p-doped), the other band edge position can be fixed from knowledge of E_g . It is important to stress that the semiconductor surface band-edge position (as estimated from V_{fb} measurements) comprises of all the terms in Eq. 10 and reflects the situation in situ for a given set of conditions (solution pH, redox concentration, etc.) of the semiconductor–redox electrolyte. The situation obviously becomes complex when the charge distribution and mediation at the interface changes either via surface states, illumination or both. These complications are considered later. Figure 8 contains the relative dispositions of the surface band-edges thus mapped for a number of semiconductors in aqueous media.

Having located the semiconductor band-edge positions (relative to either the vacuum reference or a standard reference electrode), we can also place the Fermi level of the redox system, $E_{F, redox}$, on the same diagram. Energy diagrams such as those

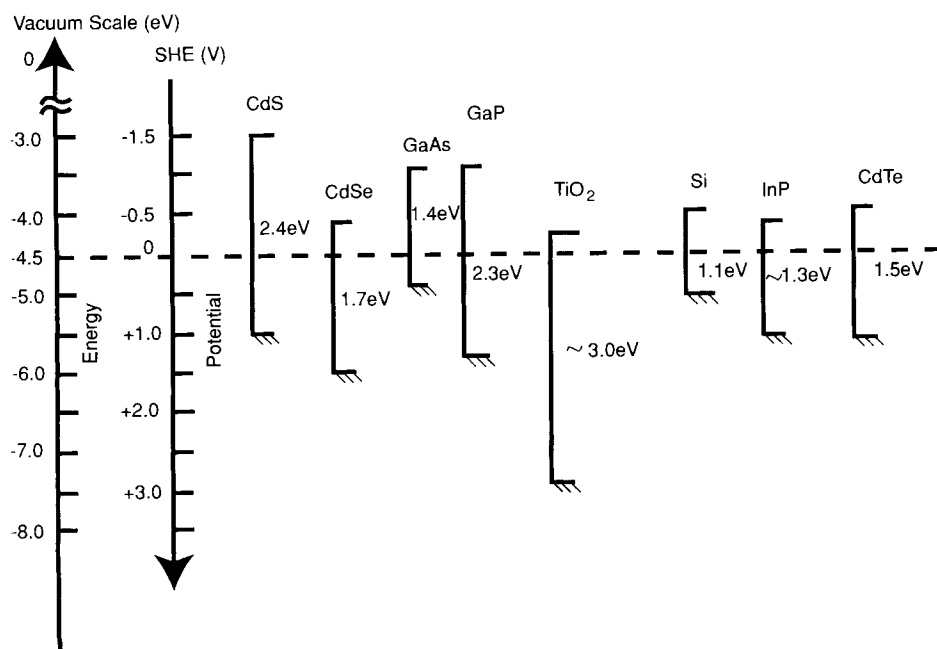

Figure 8. Relative dispositions of various semiconductor band-edge positions shown both on the vacuum scale and with respect to the standard hydrogen electrode (SHE) reference. These band-edge positions are for an aqueous medium of pH \approx 1.

Figure 9. Three situations for an n-type semiconductor–electrolyte interface at equilibrium showing overlap of the redox energy levels with the semiconductor conduction band (a) with surface states (b) and with the semiconductor valence band (c). A discrete energy level is assumed for the surface states as a first approximation.

in Figure 8 are exceedingly important in considerations of charge transfer, as we shall see later. In anticipation of this discussion, it ought already to be apparent that the three situations illustrated in Figure 9 for an n-type semiconductor–electrolyte interface entail the participation of the semiconductor conduction band, valence band and even states in its band-gap in charge exchange with the solution species. Here again is a point of departure from the metal case, viz., for a semiconductor, hole, electron and surface-state pathways must all be considered.

Let us return to the band-bending process at the interface. For a given semiconductor, the expectation is that as the redox Fermi level is moved more positive (‘down’ on the energy diagram), V_{sc} should increase concomitantly. This is the ideal (band-edge ‘pinned’) situation. In other words [23],

$$\frac{d\Delta V_{sc}}{dE_{redox}} = 1 \quad (12)$$

which reflects the fact that the change in band-bending faithfully tracks the redox potential change. A measure of the former is the open-circuit photopotential (see below). Figure 10 shows that this ideal situation indeed is realized for selected semiconductor–electrolyte interfaces [33]. As further discussed below, the analogy with the corresponding metal–semiconductor junctions (Schottky barriers) is direct [5, 34–36].

Figure 10. Plot of the open-circuit photo-voltage for amorphous Si–methanol interfaces containing a series of one-electron redox couples. (Reproduced with permission from Ref. [33].)

Complications arise when there are surface states that mediate charge exchange at the interface. When their density is high [37], they act as a ‘buffer’ in that in the extreme case, carriers in the semiconductor energy bands are completely excluded from the equilibration process.

1.3.4 Surface States and Other Complications

Surface states arise simply because of the abrupt termination of the crystal lattice at the surface; obviously, the bonding arrangement there is different from that in the bulk. Consider our prototype semiconductor, Si. The tetrahedral bonding characteristic of the bulk gives way to coordinative unsaturation of the bonds for the Si surface atoms. This unsaturation is relieved either by surface reconstruction or bonds with extraneous (e.g., solvent) species [29, 38–40]. The surface bonding results in a localized electronic structure for the surface that is different from the bulk. The energies of these localized surface orbitals nominally lie in the forbidden band-gap region. The corresponding states are thus able (depending on their energy location) to exchange charge with the conduction or valence bands of the semiconductor and/or the redox electrolyte [29].

Unlike in the case illustrated in Figure 10, changes in the solution redox potential have been observed to cause no change in the magnitude of V_{sc} . This situation is termed Fermi level pinning; in other words, the band-edge positions are *unpinned* in these cases so that the movement of E_{redox} is accommodated by V_{H} rather than by V_{sc} . As mentioned earlier, it appears [37] that surface state densities as low as 10^{13} cm^{-2} ($\sim 1\%$ of a monolayer) suffice to induce complete Fermi level pinning in certain cases. Of course, intermediate situations are possible. Thus, the ideal case manifests a slope of 1 in a plot of V_{sc} (or an equivalent parameter) versus E_{redox} (see Figure 10). On the other hand, complete pinning results in a slope of zero. Inter-

mediate cases of Fermi level exhibit slopes between 0 and 1 [41]. As stated earlier, there is a direct analogy here with the metal–semiconductor junction counterparts [42, 43]:

$$\phi_B = S\phi_m + \text{constant} \quad (13)$$

where ϕ_B is the Schottky barrier height, ϕ_m is the metal work-function and S is a dimensionless parameter. Attempts have been made to relate S to semiconductor properties [44–48].

To make matters worse, the nonideal behavior of semiconductor–electrolyte interfaces as noted above is exacerbated when the latter are irradiated. Changes in the occupancy of these states cause further changes in V_H so that the semiconductor surface band-edge positions are different in the dark and under illumination. These complications are considered later. The surface states as considered above are shallow (with respect to the band-edge positions) and can essentially be considered as completely ionized at room temperature. However, for many oxide semiconductors, the trap states may be deep and therefore are only partially ionized. Specifically, they may be disposed with respect to the semiconductor Fermi level such that they are ionized only to a depth that is small relative to W [49]. The manifestation of such deep traps in the AC impedance behavior of semiconductor electrolyte interfaces has been discussed [14, 49].

Finally, within the Mott–Schottky approximation (Eq. 11), large values of ϵ_s or N_D can lead to the ratio V_H/V_{sc} becoming significant. Figure 11 contains estimates of this ratio for several values of N_D for a semiconductor with a large ϵ_s value (TiO_2 , $\epsilon_s = 173$) mapped as a function of the total potential drop across the interface [50]. Clearly, V_H can become a sizeable fraction of the total potential drop (approaching the situation for metals) under certain conditions. It has been shown [51] that the Mott–Schottky plots will still be linear but the intercept on the potential axis is shifted from the V_{fb} value.

1.4 Experimental Methods for Studying Charge Transfer at Semiconductor–Electrolyte Interfaces

As Table 2 indicates, there is a wide array of tools available to the experimentalist to probe charge transfer at semiconductor–electrolyte interfaces. The references cited in this tabulation are meant only to provide illustrative examples of the application of a given technique, and by no means reflect a comprehensive listing. Space constraints also prohibit a detailed discussion of the principles underlying each method; the original references should be consulted instead. Several review articles [2, 4, 9, 10, 14, 52–54] have addressed the experimental aspects so that another detailed discussion here would be rather redundant. Some general comments, however, are in order prior to examining the consequences of potential- and light-induced perturbation of the semiconductor–electrolyte interface.

Figure 11. The ratio of the potential drop in the Helmholtz to the total potential change computed as a function of the total potential change. A static dielectric constant of 173 (typical of TiO_2) and a Helmholtz capacitance of $10 \mu\text{F cm}^{-2}$ were assumed and the doping density was allowed to vary from 10^{16} cm^{-3} (curve 1) to 10^{20} cm^{-3} (curve 13).

Current–potential measurements, in the dark and under illumination of the semiconductor working electrode, are extremely useful for first defining the charge-transfer behavior across the interface before more sophisticated experiments are undertaken. The irradiation can be either continuous or intermittent (chopped); the latter mode has the distinct advantage that both the dark and light behavior can be examined in the same scan [55, 58]. Even some dynamic information can thus be extracted under the nominally ‘steady-state’ conditions typical of a cyclic or linear potential sweep experiment. Another useful steady-state experiment is photocurrent spectroscopy (performed at a fixed DC potential) [55], although this can also be dynamically performed via IMPS (see below). Such measurements not only yield the so-called photoaction spectrum of the semiconductor electrode, but also afford information on surface recombination and surface state activity at the interface as discussed below.

The parameters that are measured run a wide gamut from the routine (current, potential or some electrical parameter) to the exotic (e.g., beam deflection due to refractive index changes). A hierarchical approach to discussing these variant methods has been described [52]. Thus, the methods in Table 2 fall under the categories of purely electrical (entries 1–3, 8 and 9), purely optical (entry titled photoluminescence spectroscopy and entries 12 and 13), electro-optic (electroluminescence spectroscopy) or opto-electric (entries 4–7). We can also distinguish between frequency-resolved (entries 3–7) and time-resolved (entries 10 and 14) measurements, although it must be noted that in many instances (e.g., entries 8 and 11) both steady-state and time-resolved approaches are feasible.

A relatively recent development in frequency-resolved techniques is the perturbation of an electrochemical system (that is initially in a steady-state condition) by a periodic *nonelectrical* stimulus. One member in this family of techniques (IMPS, entry 7 in Table 2) has provided a wealth of information on charge transfer across semiconductor–electrolyte interfaces. Reviews are available [2, 9, 10], as is a summary of progress on the use of its electrical predecessor (AC impedance spectroscopy, entry 3 in Table 2) for the study of these interfaces [81]. These accounts should also be consulted for a discussion of the relevant time-scales in dynamic measurements on semiconductor–electrolyte interfaces.

1.5 Charge-transfer Processes in the Dark

1.5.1 Current–Potential Behavior

Let us return to the equilibrium situation of an n-type semiconductor in contact with a redox electrolyte and reconsider the situation in Figure 9a. This is shown again in Figure 12a to underline the fact that the interface is in a state of *dynamic* equilibrium. That is, the forward and reverse (partial) currents exactly balance each other and there is no *net* current flow across the interface. In fact, the situation here is much like that at a metal–redox electrolyte interface at the rest potential. We can

Figure 12. Three situations for an n-type semiconductor–electrolyte interface at equilibrium (a), under reverse bias (b) and under forward bias (c). The size of the arrows denotes the magnitudes of the current in the two (i.e., anodic and cathodic) directions.

write expressions for the net current using a kinetics methodology as in Ref. [6] with some minor changes in notation:

$$i_c = -e_0 A k_{et} c_{ox} (n_s - n_{s0}) \quad (14)$$

where k_{et} is the rate constant for electron transfer, c_{ox} is the concentration of empty (acceptor) state in the redox electrolyte and n_s and n_{s0} are the surface concentrations of electrons, the subscript 0 in the latter case denoting the equilibrium situation. Thus, as long as the semiconductor–electrolyte interface is not perturbed by an external (bias) potential, $n_s \equiv n_{s0}$ and the net current is zero. The voltage dependence of the current is embodied in the ratio n_s/n_{s0} , which can be regarded as a measure of the extent to which the interface is driven away from equilibrium. It must be noted that n_{s0} is *not* the bulk concentration of majority carriers (n) in the semiconductor because of the potential drop across the space charge layer [6, 35]:

$$n_{s0} = n \exp\left(-\frac{e_0 V_{sc}}{kT}\right) \quad (15)$$

A few words about the units of the terms in Eq. 14 are in order at this juncture. The term $i/e_0 A$ may be regarded as a flux (J) in units of number of carriers crossing per unit area per second [1, 3, 8]. The concentration terms are in cm^{-3} ; hence k_{et} has the dimensions $\text{cm}^4 \text{s}^{-1}$ because of the second-order kinetic nature stemming from the two multiplied concentration terms in Eq. 14 [1, 3, 8].

Consider now the application of a bias potential to the interface. Intuitively, when it is such that $n_s > n_{s0}$, a reduction current (cathodic current) should flow across the interface such that the oxidized redox species are converted to reduced species ($\text{Ox} \rightarrow \text{Red}$). On the other hand, when $n_{s0} > n_s$, the current flow direction is reversed and an anodic current should flow. Once again the situation here is similar

to the metal case. The major difference resides in the vastly different state densities in the solid and the existence of an energy gap region. The two nonequilibrium situations are shown in Figure 12b and c, respectively. Away from equilibrium, we have the analogous Boltzmann expression counterpart to Eq. 15:

$$n_s = n \exp \left[-\frac{e_0(V_{sc} + V)}{kT} \right] \quad (16)$$

leading, in turn, to

$$i_c = -e_0 A k_{et} c_{ox} n_{s0} \left[\exp \left(-\frac{e_0 V}{kT} \right) - 1 \right] \quad (17)$$

The assumption is inherent in the preceding discussion that *all* of the applied bias (V) drops across the space-charge layer such that we are modulating only the majority carrier population at the surface (and not the potential drop across the Helmholtz layer). In other words, the band-edge positions are pinned or there is *no* Fermi level pinning (see Section 1.3.4).

Analogous expressions may be developed for majority-carrier flow for a p-type semiconductor in contact with a redox electrolyte with the important caveat that the valence band is involved in this process instead.

Eq. 17 suggests that the cathodic current is exponentially dependent on potential for $V < 0$. This is the so-called forward bias regime. On the other hand, when $V > 0$ (reverse-bias regime) the current is essentially independent of potential and, importantly, is of opposite sign. Simply put, in this case, the electron flow direction (i.e., anodic) is from the occupied redox states into the semiconductor conduction band (Figure 12c). It should therefore not, be surprising that this process is independent of potential. Both bias regimes are contained in curve 1 in Figure 13.

Of particular interest to this discussion is the ‘pre-exponential’ term in Eq. 17:

$$i_0 = e_0 A k_{et} c_{ox} n_{s0} \quad (18)$$

Analogous to the metal case, we can call this term the exchange current; it is the current that flows at equilibrium when the partial cathodic and anodic components exactly balance one another. Of particular interest is the dependence of i_0 on n_{s0} . Also variations in c_{ox} will affect the magnitude of i_0 . Both of these trends can be readily rationalized. Finally, i_0 will increase with doping because of the ‘thinness’ of the resultant barrier at the surface.

When $E_{F, redox}$ is moved ‘down’, i.e., more positive, the band-bending increases, V_{sc} increases and therefore n_{s0} decreases. A similar alteration in c_{ox} affects $E_{F, redox}$ through the Nernst expression. In both instances, we are influencing the Fermi level at the interface at equilibrium. Thus, in a sense, i_0 is a quantitative measure of the extent of rectification of a given interface, i.e., a smaller i_0 value translates to better rectification.

The reverse bias current remains at a very low value because of the lack of minority carriers (i.e., holes for n-type semiconductor) in the dark. Alternatively,

Figure 13. Current–potential curves for an n-type semiconductor in the dark (curve 1) and under band-gap illumination (curves 2 and 3). Two levels of photon fluxes are shown in the latter case.

injection of electrons from occupied redox levels (also an anodic current) has to thermally surmount the surface barrier [5, 34, 35]. Under extreme reverse bias, however, this barrier becomes ‘thin’ and electrons can tunnel through it leading to an abrupt increase in the anodic current. This process was studied even in the early days of semiconductor electrochemistry (see, e.g., Ref. [156]) and a detailed discussion can be found in a book chapter [14]. Ultimately the junction ‘breaks down’ (at the so-called Zener limit). This dark current flow is not shown in Figure 13 (curve 1).

Returning to the forward bias (cathodic) current flow, Eq. 17 bears some analogy to the famous Tafel expressions in electrochemical kinetics. Thus, ignoring the unity term within the square brackets, Eq. 17 predicts a Tafel slope of 60 mV per decade at 298 K. In many instances (see, e.g., Refs. [157, 158]), such a slope indeed is observed. In many cases, however, the slopes are higher than the ‘ideal’ value [14, 159–163].

The causes of this anomalous behavior are still not fully understood. It appears likely that many factors are involved: surface film formation, varying potential drop across the Helmholtz region caused, for example, by surface state charging, etc. Even crystallographic orientations appear to be important [163]. These aspects have been discussed by other authors [14, 159, 164].

We have so far considered only (majority carrier) processes involving the CB (again assuming for illustrative purposes an n-type semiconductor). Consider the interfacial situation depicted in Figure 9c. The energy states of the redox system now overlap with the VB of the semiconductor such that *hole injection* in the ‘dark’ is possible. When the band-bending is large, the injected holes remain at the surface and attack the semiconductor itself, causing the latter to undergo corrosion. If the

Figure 14. Hole injection into the VB of an n-type semiconductor from an oxidant (e.g., Fe^{3+}) and the injection/recombination pathway. Both surface-state mediated and depletion layer trap mediated routes are shown for the recombination.

bias potential is such that the band-bending is modest and the holes recombine with electrons (either via the surface states or in the space-charge region itself), a cathodic current flows that is carried by the majority carriers in the bulk. This recombination current pathway is schematized in Figure 14 and is further discussed in the next section. Hole injection has been extensively studied especially for III–V (Group 13–15) semiconductors such as GaAs and GaP because of the relevance of this process to electroless etching and device fabrication technology. This topic has been reviewed [165–168].

The invocation of either the conduction band or the valence band of the semiconductor in charge exchange in the dark with solution redox species is not always straightforward. This is particularly true for multi-electron redox processes to be discussed later. Movement of the semiconductor band-edge positions (i.e., band-edge unpinning) relative to the redox energy levels also presents a complicating situation (see below). Some cases (e.g., $\text{Eu}^{2+/3+}$ in contact with GaAs electrodes) are interesting in that the same couple can interact with both bands [159, 169]. Thus the oxidation of Eu^{2+} is a VB process (occurring at p-GaAs but not at n-GaAs in the dark), while the reduction of Eu^{3+} (a facile process reportedly occurring at rates close to the thermionic emission limit [159]) is mediated by CB electrons [169]. The $[\text{Cr}(\text{CN})_6]^{3-/4-}$ redox system behaves in a similar manner with respect to GaAs [170].

Electroluminescence, EL (Table 2), is a versatile probe for studying such carrier injection processes. Thus, hole injection into the VB of an n-type semiconductor leads to cathodic EL whereas electron injection into the CB of a p-type semiconductor leads to anodic EL [171]. Examples of studies of cathodic EL are common-

Figure 15. Surface-state mediated electron injection from the CB of an n-type semiconductor into the electrolyte.

place (e.g., [129, 172, 173]); however, anodic EL is not very common because of the energy requirement for the redox couple to have a very negative redox potential. Nonetheless, anodic EL has been reported for the p-InP–[Cr(CN)₆]⁴⁻ interface [174]. Radical intermediates can also cause EL as discussed later for multi-electron redox processes.

This finally brings us to the comparability of the current–potential behavior of n- and p-type samples of a given semiconductor. It may be noted that for a redox process occurring via one of the bands (e.g., VB), the cathodic currents (electron transfer from VB to Ox) are expected to be equal for n- and p-type materials. This idea has been pursued using the so-called quasi-Fermi level concept [159, 175, 176]. This model has been proven quantitatively by studying the anodic decomposition of GaAs and the oxidation of redox species such as Cu⁺ and Fe²⁺ at n- and p-type GaAs electrodes [175, 176]. The original references should be consulted for details.

1.5.2 Dark Processes Mediated by Surface States or by Space Charge Layer Recombination

Surface states were considered earlier (Section 1.3.4) from an electrostatic perspective. Here we examine their dynamic consequences. There are two principal charge-transfer routes involving surface states. Consider again an n-type semiconductor; the forward bias current can either involve direct exchange of electrons between the semiconductor CB and Ox states in solution (see Figure 12b) or can be mediated by surface states (Figure 15). The second route involves hole injection into the semiconductor VB, again from Ox states in solution (Figures 9c and 14). The recomb-

(a)

(b)

Figure 16. Equivalent circuit (a) and a simulated Nyquist plot (b) for the charge transfer pathway illustrated in Figure 15. The capacitance C_1 represents that of the space-charge layer and the parallel branch components represent the Faradaic charge transfer process. Refer to the original work for further details. (Reproduced with permission from Ref. [84].)

nation current is mediated either by surface states or via space-charge layer recombination. We shall consider first the CB process.

Initial evidence for the intermediacy of surface states came from dark current measurements on n-TiO₂ and n-SrTiO₃ in the presence of oxidizing agents such as [Fe(CN)₆]^{3−}, Fe³⁺, and [IrCl₆]^{2−} [177, 178]. Similar evidence that the charge-transfer process was more complex than direct transfer of electrons from the semiconductor CB also came early from AC impedance spectroscopy measurements on n-ZnO, n-CdS and n-CdSe in contact with [Fe(CN)₆]^{3−} species [179, 180].

Figure 17. Equivalent circuit representation of the injection/recombination process. (Reproduced with permission from Ref. [81].)

The electrochemical impedance for surface state-mediated charge transfer has been computed recently [84]. The key results are summarized in Figure 16. Figure 16a contains the proposed equivalent circuit for the process and features a parallel connection of the impedance for the Faradaic process [$Z_F(\omega)$] (ω = angular frequency, $2\pi f$) and the capacitance of the semiconductor depletion layer, C_{sc} . The former also involves a diffusion impedance (Δ) of the Warburg type (see below). The complex plane (Nyquist) plot predicted for the circuit is illustrated in Figure 16b. The theoretically predicted AC impedance response was compared with experiments on n-GaAs rotating disk electrodes in sulfuric acid media [85]. The equivalent circuit in Figure 16a was also compared with previous versions proposed by other authors [181–183]. These alternative versions differ in their assumption of no variations in potential drop across the Helmholtz region (i.e., infinite C_H) and no concentration polarization in the electrolyte phase (infinite diffusion coefficient for the redox species). The same research group has also discussed the application of AC impedance spectroscopy for studying the kinetic reversibility of majority carrier charge transfer via the CB of an n-type semiconductor [83]. These original references should be consulted for further details.

AC impedance spectroscopy also has seen extensive utility in the study of the hole injection/recombination process depicted in Figure 14. An equivalent circuit for this process is illustrated in Figure 17; it resembles the circuit in Figure 16a except for the Warburg component [81]. Early studies [73, 74, 184, 185] utilized the recombination resistance parameter, R_r , that was extracted from model fits of the measured AC impedance data. This parameter was seen to be inversely related to the hole injection current, thus signifying that it is indeed related to the recombination process. However, the challenge is to differentiate whether recombination is mediated via surface states or whether it occurs in the depletion layer. Thus the parameter R_r alone cannot afford this information and both the real and the imaginary parts of this additional impedance must be considered. Subsequent studies have addressed this aspect [73, 186–190]. The admittance corresponding to recombination at the surface [189] and in the space-charge layer [190] was calculated from first principles. These computations show that the recombination *capacitance* increases monotonically with decreasing band-bending in the latter case while it shows a peak in the former case as a function of potential.

Experimental studies [188] show that in the case of n-GaAs electrodes in contact with Ce^{4+} as the hole injection agent, surface recombination prevails. On the other hand, with n-GaP electrodes, recombination in the depletion layer must also be

taken into account. Other discussions of the use of AC impedance spectroscopy for the study of hole injection/ recombination are contained in Refs. [81] and [84].

The consequences of potential drop variations across the Helmholtz layer in the hole injection process have been examined by a variety of techniques [191, 192]. For example, chemical reaction of the GaAs surface with iodine results in a downward shift of the semiconductor band-edge positions such that the reduction of iodine is mediated by conduction band electrons [192]. When sufficient negative charge accumulates at the surface, the potential is redistributed between the semiconductor space-charge layer and the Helmholtz region. Now iodine is reduced by hole injection as gauged by EL and AC impedance measurements [192].

1.5.3 Rate-limiting Steps in Charge-transfer Processes in the Dark

The assumption is implicit in the discussion in Section 1.5.1 (leading to Eq. 18) that charge-transfer kinetics at the semiconductor–electrolyte interface is the rate-limiting step. Fundamentally, we have to differentiate majority carrier *capture* and minority carrier *injection* processes in the dark. In the former case, transit through the semiconductor itself or charge exchange with the surface states can be potentially rate-limiting. In the latter case, there are three steps involved: hole injection into the semiconductor VB, charge exchange between the recombination center and the semiconductor CB and diffusion of majority carriers (electrons) from the neutral region. Finally, mass transport processes in the electrolyte phase itself can be a limiting factor in the overall current flow. We shall examine carrier capture and injection processes in turn.

Most outer-sphere, nonadsorbing redox systems to date have yielded values for k_{et} in the 10^{-17} – 10^{-16} $\text{cm}^4 \text{s}^{-1}$ range [3, 8]. These include n-Si–CH₃OH [193, 194], n-InP–CH₃OH [195], GaInP₂-coated n-GaAs–acetonitrile [196] and p-GaAs–HCl [197] interfaces. The redox couples in these studies have mostly involved metal-locenes that show a low proclivity to adsorb on the semiconductor surface. In these cases, the rate-determining step in the overall current flow undoubtedly lies in the electron transfer event at the interface itself. However, values for k_{et} roughly three orders of magnitude higher have also been reported for similar interfaces, e.g., n-GaAs–acetonitrile containing cobaltocenium [$\text{Co}(\text{Cp})_2^+$] acceptors [196, 198]. Similarly, high values were reported for p-GaAs–acetonitrile interfaces with ferrocenium and cobaltocenium redox species [199]. In these latter cases, alternative mechanisms (e.g., thermionic emission, see below) must be invoked in a rate-limiting role. Quartz crystal microbalance (Table 2) measurements have yielded evidence for adsorption of redox species (and consequently high *local* substrate concentration) in some of these ‘anomalous’ instances [198].

In the majority carrier capture process, if the interfacial charge-transfer kinetics are facile, the transport of majority carriers through the space-charge region can play a rate-limiting role. The thermionic emission theory [34] assumes that every electron that reaches the semiconductor surface and has the appropriate energy to overcome the potential barrier there will cross the interface with a tunnel probability of unity. However, if the interfacial kinetics are sluggish, some of the electrons will be reflected at the interface. In this case, the exchange current i_0 is no longer

described by Eq. 18 but by Eq. 19 [34]:

$$i_0 = AA^* \left(\frac{m^*}{m_e} \right) T^2 \left(\frac{n_s}{n} \right) \quad (19)$$

where A is the electrode area, A^* is the Richardson constant ($120 \text{ A K}^{-2} \text{ cm}^{-2}$), m^*/m_e is the relative effective electron mass in the conduction band and T is the absolute temperature.

In many of the reported instances [157, 159, 200], the current calculated from Eq. 19 is much higher than that measured experimentally, signaling that interfacial charge-transfer kinetics are limiting the overall rate. On the other hand, in the n-GaAs–acetonitrile– $\text{Co}(\text{Cp})_2^+$ case [198], AC impedance spectroscopic data appear to support the assumption that thermionic emission is the current-limiting transport mechanism.

Another factor that enters into this discussion is the mobility of the majority carriers. It has been argued [14] that in the case of low-mobility materials (e.g., $\mu_n \approx 1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$), carrier transport from the semiconductor bulk to the interface itself can become limiting. Clearly, a multitude of factors are important in majority carrier capture: k_{et} , acceptor concentration in the electrolyte and carrier mobility.

What about the minority carrier injection process depicted in Figure 14? Here, contrasting with the process considered above, the hole injection step itself is usually very fast (see below). Then the current is limited by diffusion/recombination described by the Shockley equation [201]:

$$i_0 = \frac{e_0 A D_p n_i^2}{n L_p} \quad (20a)$$

for bulk recombination and

$$i_0 = 0.5 e_0 A W \sigma v_{\text{th}} N_t n_i \quad (20b)$$

for recombination within the semiconductor space-charge region, where D_p is the diffusion coefficient for holes, L_p is the hole diffusion length, n_i is the intrinsic carrier concentration, σ is an average capture cross-section for electrons and holes, v_{th} is the thermal velocity of charge carriers and N_t is the areal density of recombination (trap) centers in the middle of the energy gap (see Figure 14).

The diffusion/recombination mechanism results in considerable overpotential for (cathodic) current flow in the dark (again assuming an n-type semiconductor for illustration). Such a rate-limiting process was found to describe the charge transfer at n-GaAs in 6 M HCl containing Cu^+ as the hole-injecting species [159, 176].

Whatever the limiting mechanism, ultimately the current becomes limited by concentration polarization, i.e., by the transport of redox species from the bulk electrolyte to the semiconductor surface. The situation in this regard is no different from that at metal electrode–electrolyte interfaces. As in the latter case, hydrodynamic (specifically RDE, Table 2) voltammetry is best suited to study mass transport. AC impedance spectroscopy can be another useful tool in this regard [82].

In the former case, the data can be processed via Levich plots of current vs. $\omega^{1/2}$ (ω = angular frequency). If processes other than solution mass transport become rate-limiting, then the plot will show a curvature and the current will even become independent of the electrode rotation rate. In this case, inverse Levich (or Koutecky–Levich) plots of $1/i$ vs. $\omega^{-1/2}$ can be used for further analyses. Such analyses have been done, for example, for n-GaAs–acetonitrile– $\text{Co}(\text{Cp})_2^+$ interfaces [198] and n- and p-GaAs electrodes in contact with the $\text{Cu}^{+/2+}$ redox couple in HCl electrolyte [159, 176].

The diffusion impedance at semiconductor electrodes has been considered recently [82]. Hens and Gomes described the applicability of AC impedance spectroscopy for the study of electron capture and hole injection processes at n-GaAs– $\text{H}_2\text{O}/\text{C}_2\text{H}_5\text{OH}$ –methylviologen, p-InP–aq. KOH – $\text{Fe}(\text{CN})_6^{3-}$, n-GaAs– H_2SO_4 – Ce^{4+} and n-InP–aq. KOH – $\text{Fe}(\text{CN})_6^{3-}$ interfaces. In the case of electron-capture processes, a Randles-like equivalent circuit was found to be applicable [82]. On the other hand, no Warburg component was present in the hole injection case when the reverse reaction was negligible (see Figure 17). For a nonideal semiconductor–electrolyte contact (see Section 1.3.4), a Warburg impedance appeared in the electrochemical impedance of an injection reaction as well, as exemplified by the n-InP– $\text{Fe}(\text{CN})_6^{3-}$ case [82].

1.6 Light Absorption by the Semiconductor Electrode and Carrier Collection

1.6.1 Light Absorption and Carrier Generation

The optical band-gap of the semiconductor (Section 1.2) is an important parameter in defining its light absorption behavior. In this quantized process, an electron–hole pair is generated in the semiconductor when a photon of energy $h\nu$ (ν = frequency and $h\nu > E_g$) is absorbed. Optical excitation thus results in a delocalized electron in the CB, leaving behind a delocalized hole in the VB; this is the band-to-band transition. Such transitions are of two types: direct and indirect. In the former, momentum is conserved and the top of VB and the bottom of CB are both located at $k = 0$ (k is the electron wavevector). The absorption coefficient (α) for such transitions is given by [202]

$$\alpha = A'(h\nu - E_g)^{1/2} \quad (21)$$

where A' is a proportionality constant. Indirect transitions involve phonon modes; in this case, Eq. 21 takes the form

$$\alpha = A'(h\nu - E_g)^2 \quad (22)$$

A given material can exhibit a direct or indirect band-to-band transition depending

on its crystal structure. For example, Si single crystals have an indirect transition located at 1.1 eV (Table 1). On the other hand, amorphous Si is characterized by a direct optical transition with a larger E_g value (shorter wavelengths). Even both types of transitions can be seen in the same material, e.g., GaP [203].

Within the present context, the important point to note is that the absorption depths (given by $1/\alpha$) are vastly different for direct and indirect transitions. Whereas in the former case absorption depths span the 100–1000 nm range, they can be as large as 10^4 nm for an indirect transition [9].

Optical transitions in semiconductors can also involve localized states in the band-gap. These become particularly important for semiconductors in nanocrystalline form (see below). Sub-band-gap transitions can be probed with photons of energy below the threshold defined by E_g .

1.6.2 Carrier Collection

The number of carriers collected (in an external circuit, for example) versus those optically generated defines the quantum yield (Φ), a parameter of considerable interest to photochemists. The difficulty here is to quantify the amount of light actually absorbed by the semiconductor since the cell walls, the electrolyte and other components of the assembly are all capable of either absorbing or scattering some of the incident light. Unfortunately, this problem has not been comprehensively tackled, unlike in the situation with photocatalytic reactors involving semiconductor particulate suspensions where such analyses are available [204–207]. Pending these, an *effective* quantum yield can still be defined.

Returning to the carrier collection problem, consider Figure 18 for an n-semiconductor–electrolyte interface. As can be seen, the electron–hole pairs are optically generated, both in the field-free and in the space-charge regions within the semiconductor. Recombination of these carriers must be considered in the bulk, in the space-charge layer and on the semiconductor surface (the latter in contact with the redox electrolyte). We are assuming here that light is incident from the electrolyte side. Rear illumination geometry can be profitably employed and is considered later for the nanocrystalline film case.

The direction of the electric field at the interface (Figure 6, Section 1.3.2) is such that the minority carriers (holes in this case) are swept to the surface and the electrons are driven to the rear ohmic contact. How fast the holes are drained away (by Faradaic reactions involving the redox electrolyte) will dictate how the Fermi levels compare with the equilibrium situation discussed earlier. The departure from equilibrium has been quantified in terms of the quasi-Fermi level concept discussed later.

The extent of collection of minority carriers from the region beyond the depletion layer is dictated by the diffusion process. A diffusion length, L , can be defined:

$$L_p = \sqrt{D_p \tau_p} = \sqrt{kT \mu_p \tau_p} \quad (\text{for n-type semiconductor}) \quad (23)$$

The subscripts in Eq. 23 remind us that we are dealing with minority carrier col-

Figure 18. Photogeneration of electron–hole pairs in the field-free region and depletion layer for an n-type semiconductor–electrolyte interface. The characteristic regions defined by the depletion layer (W), Debye length (L_D) and the light penetration depth ($1/\alpha$) are also compared.

lection; μ_p is the hole mobility and τ_p is the hole lifetime. The characteristic length L_p defines the region within which electron–hole pair generation is fully effective. Thus, pairs generated at depths longer than the Debye length, L_D ($L_D = W + L$), will simply recombine. Thus, the effective quantum yield for a given interface will depend on the relative magnitudes of L_D and the light penetration depth, $1/\alpha$ (Figure 18) [9, 54, 55].

An expression for the flux of photogenerated minority carriers arriving at the surface was originally given for a solid-state junction [208] and subsequently adapted to semiconductor–liquid junctions [209]. The major weakness of these initial models hinges on their underlying assumption for the boundary condition that the surface concentration of minority carriers is zero. As pointed out elsewhere [14], this is a demanding condition necessitating very high magnitudes for the interfacial charge transfer rate constant, k_{et} (see above). A modicum of improvement to the basic Gärtner model was found [210] by defining a flux rather than a concentration expression for the holes and a characteristic length where the bulk diffusion current transitions into a drift current. However, this treatment still assumes that every hole

entering the depletion layer edge exits this region and out into the electrolyte phase.

The Gärtner equation [208] can be written in normalized form [55]:

$$\Phi \equiv \frac{j_{ph}}{I_0} = 1 - \frac{\exp(-\alpha W)}{1 + \alpha L_p} \quad (24)$$

where Φ is the effective quantum yield (see above), given by the ratio of the photo-current density (i_{ph}/A), j_{ph} , to the incident light flux, I_0 . Recasting Eq. 24 in the form

$$-\ln(1 - \Phi) = \ln(1 + \alpha L_p) + \alpha W \quad (25)$$

recalling that W is proportional to $V_{sc}^{1/2}$ (Eq. 8) and $V_{sc} = V - V_{fb}$, a test of the rudimentary model would lie in a plot of the left-hand side of Eq. 25 against $(V_{fb} - V)^{1/2}$. Such plots are shown in Figure 19 at four selected wavelengths for the p-GaP-H₂SO₄ electrolyte interface [211].

While adherence to the Gärtner model is satisfactory for large values of V_{sc} (i.e., large band-bending, see Figure 6), the model clearly fails close to the flat-band situation. Interestingly, this problem is exacerbated as the semiconductor excitation wavelength becomes shorter (Figure 19). Thus, another weakness of the basic Gärtner model [208, 209] is the complete neglect of surface recombination. At the

Figure 19. Gärtner plots (see Eq. 25) for the p-GaP-0.5 M H₂SO₄ interface. The numbers on the plots refer to the excitation wavelength; E_{fb} is the flat-band potential and E is the bias potential. (Note that this notation is different from that employed in the text.) (Reproduced with permission from Ref. [211].)

Figure 20. Comparison of calculated current voltage profiles in the dark (curve d) and under illumination (curves a–c). Curve a is obtained from the basic Gärtner model. Curve b considers surface recombination and curve c considers both surface recombination and recombination in the space-charge layer. These simulations are for an n-type semiconductor–electrolyte interface. (Reproduced with permission from Ref. [230].)

flat-band situation, this model still predicts finite current flow arising from the diffusive flow of minority carriers toward and out of the interface (see Figure 20).

A variety of refinements have been made to take into account the surface recombination effect [93, 211–225]. The earliest of these [212, 213, 216] involve some simplifying assumptions:

- 1) there is no recombination in the depletion layer, that is, all the holes optically generated in the bulk and within the depletion layer (Figure 18) are swept to the surface without loss;
- 2) the steady-state concentration of the optically generated minority carriers does not perturb the potential distribution in the dark (Figure 6); and
- 3) there is a quasi-thermodynamic distribution of minority carriers within the depletion layer, which translates to a constant product term np across this region.

Surface recombination in most of these treatments invokes the Hall–Shockley–Read model [226, 227]. Defining the Gärtner limiting expression (Eq. 24) as Φ_G , we obtain [14]

$$\Phi_{ss} = \Phi_G \left/ \left[1 + \frac{D_p \exp V_{sc}}{L_D(k_t + S_t)} \right] \right. \quad (26)$$

In Eq. 26, we have two new parameters, k_t and S_t . These are the first-order rate constant for hole transfer (units of cm s^{-1} , see below) and the surface recombination

Figure 21. Surface-state mediation of both minority carrier (i.e., hole) transfer and recombination for an n-type semiconductor electrolyte interface.

velocity, S_t , respectively. In the combined situation of high L_D , high k_t and very low (or zero) S_t , Eq. 26 collapses to the Gärtner limit.

At this juncture, it is worth noting that only one trap state at the surface has been assumed until now; further, it is assumed that this surface state both functions as a carrier recombination site and as a charge transfer pathway (Figure 21). Both of these assumptions are open to criticism. An alternative model invoking two distinct types of surface states, one active in recombination and the other capable of mediating charge transfer, has been considered [228]. Nonetheless, the most serious flaw in the treatments above lies in the neglect of carrier recombination in the depletion layer itself (as distinct from recombination at the surface). Re-examination of Eqs. 24 and 26 shows that the larger the Debye length, L_D , and the depletion layer width, W , the higher is the quantum yield. However, recombination in the space-charge layer must become significant at some value of W , thus providing a further limit to carrier collection.

Recombination within the space-charge region is a non-trivial problem to treat from a computational perspective [14]. The methodology of Sah, Noyce, and Shockley [229] has been used by several authors [219, 220, 223, 230–232]. Figure 20 illustrates the sensitivity of the current–potential profiles at the semiconductor–electrolyte interface to this recombination mode [230].

Other models taking the above nonidealities to varying extents have been proposed; a detailed discussion of these lies beyond the scope of this chapter [233–239]. However, it is worth noting here that in some instances involving high-quality semiconductor–electrolyte interfaces the rate-determining recombination step does

indeed appear to lie in the bulk semiconductor [1, 240]. Silicon photoelectrodes in methanolic media containing fast, one-electron, outer-sphere redox couples were studied in these cases.

1.6.3 Photocurrent–Potential Behavior

The current–voltage characteristics of an illuminated semiconductor electrode in contact with a redox electrolyte can be obtained by simply adding together the majority and minority current components. The majority carrier component is given by the diode equation (Eq. 17) while the minority carrier current (i_{ph}) is directly proportional to the photon flux (see, e.g., Eq. 24). Thus, the net current is given by

$$i = i_{\text{ph}} - i_0 \left[\exp\left(-\frac{e_0 V}{kT}\right) - 1 \right] \quad (27)$$

The minus sign in Eq. 27 underlines the fact that the majority-carrier component flows opposite to (or ‘bucks’) the minority carrier current flow. This photocurrent component is shown as curves 2 and 3 in Figure 13.

Eq. 27 shows that the diode equation is offset by the i_{ph} term; this is exactly what is seen in Figure 13. The plateau photocurrent is proportional to the photon flux, I_0 , as illustrated for two different values of the incident light intensity in Figure 13. At the open-circuit condition of the interface, $i = 0$ (and neglecting the unity term within the square brackets relative to the exponential quantity), Eq. 27 leads to

$$V_{\text{oc}} \approx \frac{kT}{e_0} \ln\left(\frac{i_{\text{ph}}}{i_0}\right) \quad (28)$$

Eq. 28 underlines two important trends: first, V_{oc} increases logarithmically with the photon flux (with a slope of ~ 60 mV at 298 K). Second, V_{oc} decreases with an increase in i_0 (again logarithmically). This underlines the importance of ensuring that the majority carriers do not ‘leak’ through the interface. Because of the diode nature of the interface, from a device perspective, the semiconductor surface must be designed to have fast minority carrier transfer kinetics (and thus high i_{ph}) but must be blocking to the flow of majority carriers (from the CB for an n-type semiconductor) into the redox electrolyte. This challenge is not unlike what solid-state device physicists face but relative to metals (with a high density of acceptor states), *chemical* control of redox electrolytes offers a powerful route to performance optimization of liquid-based interfaces, as also pointed out by previous authors [1, 6, 8].

Referring back to Figure 13, the current–potential curves under illumination of the semiconductor simply appear shifted ‘up’ relative to the dark i – V counterpart. This, however, is the ideal scenario. Anomalous photoeffects (APEs) are often observed that manifest as a cross-over of light and dark current–voltage curves, as illustrated in Figure 22. Thus, the superposition principle [241] is not obeyed in this instance. The dashed line in Figure 22 is produced by translating the photocurrent–

Figure 22. Anomalous photoeffect (APE) showing cross-over of the dark and light current–voltage curves for an n-type semiconductor-based interface. The dashed line is obtained as described in the text.

voltage data by j_{sc} , the short-circuit current density. If the superposition principle held, this dashed curve would have overlaid the dark current–voltage curve. Hence this ‘excess’ (forward bias) current embodies the APE, and the failure of superposition is quantified as the voltage difference (ΔV) between the dark j – V data and the dashed line.

What are the ramifications of the cross-over or the APE? First, mathematical modeling of carrier transport in a junction-based solar photovoltaic system, according to

$$j = j_{sc} - j_{bk}(V) \quad (27a)$$

not valid in the presence of this effect. (In Eq. 27a, j_{bk} is the ‘bucking’ current density in the forward-bias regime; see above.) That is, a fully linearized system of differential equations plus boundary conditions cannot be used to model the interface carrier transport. Second, computation and modeling of the open-circuit voltage for such devices by simply equating a constant photocurrent flux, j_{ph} , against the dark (recombination) current, j_0 , is no longer possible (see Eq. 28 and the accompanying discussion above).

Third, and perhaps practically of most significance, the ΔV component represents a loss pathway in the photovoltage deliverable by the given device. Thus, the (open-circuit) photovoltage is V_{oc} instead of $V_{oc} + \Delta V$ in the ideal case in the absence of the APE. Therefore, it is important to quantify and understand the molecular and chemical origins of this effect. This has not been done so far, at least to this writer’s knowledge, for semiconductor–electrolyte interfaces.

Of course, the cross-over effect is not confined to such interfaces. It is interesting that a recent textbook [241], dealing primarily with solid-state solar cell devices, makes only a fleeting reference to the underlying origin of the APE. Reference was made in this book to the cross-over of experimental dark and light j – V characteristics for a Cu_2S – CdS solid-state heterojunction solar cell but its origin was not

explored. A light-induced junction modification has also been reported for the (Cd,Zn)S–CuInSe₂ solid-state system [242]. The cross-over effect appears to have been treated in even lesser depth in some classical textbooks on semiconductor devices [201, 243].

Probably the first reported instance of observation of an APE was in 1977 for an n-TiO₂–NaOH electrolyte interface [244]. The APE was observed in the saturation region of cathodic current flow and was induced by sub-band-gap irradiation of the photoanode. A peak in the spectrum of the photoresponse at 800 nm (the corresponding photon energy being lower than the 3.0 eV bandgap of TiO₂) was used by the authors to invoke a surface-state mediated electron transfer to O₂ (in the electrolyte) as the origin of the photoeffect. Surface states were again invoked to explain a cathodic photoeffect at n-CdS–aqueous polysulfide interfaces [245]. This photoeffect was only observed for the (0001) single crystal face of n-CdS but not for the (0001) orientation. A subsequent study of photoelectrochemical effects at selenium films reported an anomalous *anodic* photocurrent at potentials positive of the flat-band location for the p-type film [246]. This effect was assigned to a hole injection process via a tunneling mechanism. An increase in the tunneling probability under illumination was accommodated by a shrinking of the space-charge layer at the interface. Photoenhancement of the forward current flow was observed again for n-CdS, in this instance in contact with a [Fe(CN)₆]^{3–/4–} redox electrolyte [247]. This effect was observed only with a mechanically damaged surface, and disappeared after it had been etched with concentrated HCl.

Subsequent work [248] describes suppression of the cathodic photocurrent for n-CdS–[Fe(CN)₆]^{3–/4–} interfaces upon mechanical polishing of the electrode. As with an earlier study [244], the spectral dependence of the photocathodic effect implicated sub-band-gap states. The suppression was explained by two alternative models involving a compensated insulating layer or by Fermi-level pinning. Illumination was claimed to result in a dramatic increase in the (suppressed) cathodic current, which interestingly enough was observed only for n-CdS films but not for crystals, including n-CdTe, n-CdSe, n-GaAs, n-ZnO, n-TiO₂ and n-ZnSe. On the other hand, a subsequent paper describes a photocathodic effect for n-CdSe–sulfite interfaces in which an interfacial layer of selenium was implicated [249].

More recent studies on n-CdS [250, 251] and n-TiO₂ photoanodes [252] implicate the formation of photoconductive layers in the APEs. Thus, the foregoing review suggests the following:

- 1) the APE is a very general phenomenon that has been observed for solid-state junctions for n- and p-type semiconductors alike, and for a wide variety of semiconductor materials;
- 2) the reported results and trends are often contradictory; it is possible that the experimental conditions in these studies were variant, thus precluding direct comparison of the results;
- 3) the mechanistic reasons given for the APE are possibly many and generalizations may not be warranted. Clearly, more research is needed on this topic.

Figure 23 contains an example of the APE for the n-GaAs–AlCl₃/n-butylpyridinium chloride molten salt electrolyte interface [253]. The bottom curve is

Figure 23. Experimental data embodying APE for the n-GaAs– AlCl_3 /n-butylpyridinium chloride molten-salt electrolyte interface. Refer to the text for details. (Reproduced with permission from Ref. [253].)

the measured dark current–voltage profile. The top curve was obtained from the photocurrent–voltage data (under irradiation of the semiconductor). Clearly, if the superposition principle held, the two curves would have coincided with one another.

APEs have also been observed for nanocrystalline and chemically modified films, as discussed in a subsequent section.

Light-induced changes in the electrostatics at the semiconductor–electrolyte interface are conveniently probed by capacitance–voltage measurements in the dark and under illumination of the semiconductor electrode. If charge trapping at the interface plays a decisive role (whatever be the mechanism), the voltage drop across the illuminated interface is altered, and consequently the semiconductor band-edge positions are shifted. This, of course, is the Fermi-level pinning situation that was encountered earlier (Section 1.3.4). Such measurements have been performed for a variety of interfaces and one example is shown in Figure 24 [217]. Another example concerns the CdTe–aqueous electrolyte interface [254].

1.6.4 Dynamics of Photoinduced Charge Transfer

So far, the discussion has centered on the steady-state aspects of carrier generation and collection at semiconductor–electrolyte interfaces. As with their metal electrode

Figure 24. Mott–Schottky plots in the dark (i) and under illumination (ii) for a p-GaAs–0.5 M H₂SO₄ interface. The insert quantifies the shift in V_{fb} versus the limiting photocurrent density (or equivalently the photon flux). (Reproduced with permission from Ref. [217].)

counterparts, a wealth of information can be gleaned from perturbation–response type of measurements. An important difference, however, lies in the vastly different time-scale windows that are accessible in the two cases. The critical RC time constant of the cell in a transient experiment is given by

$$\tau_{\text{cell}} = C(R_m + R_{\text{el}}) \quad (29)$$

where R_m is the resistance of the measurement resistor (across which the current or photocurrent is measured) and R_{el} is the electrolyte resistance. The term C is the capacitance, which, in the metal case, is the Helmholtz layer capacitance, C_H . (Once again, the Gouy region is ignored here.) For semiconductor–electrolyte interfaces, we have seen that two layers are involved in a series circuit configuration with corresponding capacitances of C_{sc} and C_H (Figure 6). Since $C_H \gg C_{\text{sc}}$, $C \approx C_{\text{sc}}$. This assumption is usually justified since $C_H \approx 10^{-5} \text{ F cm}^{-2}$ and $C_{\text{sc}} = 10^{-8} \text{--} 1 \text{ F cm}^{-2}$. If the composite resistance ($R_m + R_{\text{el}}$) is 100Ω then τ_{cell} for metal electrodes is $\sim 10^{-3} \text{ s}$ and that for the semiconductor case is $10^{-6} \text{--} 10^{-7} \text{ s}$.

What are the processes important in a dynamic interrogation of the semiconductor–electrolyte interface? They are

- 1) carrier generation within the semiconductor;
- 2) diffusion of minority carriers from the field-free region to the space-charge layer edge;
- 3) transit through this layer;
- 4) charge transfer across the interface; and
- 5) carrier recombination via surface states or via traps in the space-charge layer.

Other phenomena such as thermalization also are important, as discussed below within the context of hot carrier effects. Complicating matters further and one that has caused some confusion in the interpretation of transient data is the time constant (τ_{cell}) of the cell and the measurement circuitry. If a potentiostat is not used, then this time constant is given by Eq. 29.

One can envision three types of perturbation: an infinitesimally narrow light pulse (a Dirac or δ -function), a rectangular pulse (characteristic of chopped or interrupted irradiation) or periodic (usually sinusoidal) excitation. All three types of excitation and the corresponding responses have been treated on a common platform using the Laplace transform approach and transfer functions [255]. These perturbations refer to the temporal behavior adopted for the excitation light. However, classical AC impedance spectroscopic methods employing periodic potential excitation can be combined with steady-state irradiation (the so-called PEIS experiment). In the extreme case, both the light intensity and potential can be modulated (at different frequencies) and the (nonlinear) response measured at sum and difference frequencies. The response parameters measured in all these cases are many but include the photocurrent, voltage, luminescence or microwave conductivity. Clearly semiconductor–electrolyte interfaces present a rich, albeit demanding, landscape for probing non-steady-state phenomena.

Perhaps the simplest to discuss is the rectangular excitation waveform. In fact, this method can even be combined with a slow voltammetric scan upon which the chopped irradiation response appears superimposed. This ‘photovoltammetry’ experiment is schematized in Figure 25. Two types of transient responses are apparent.

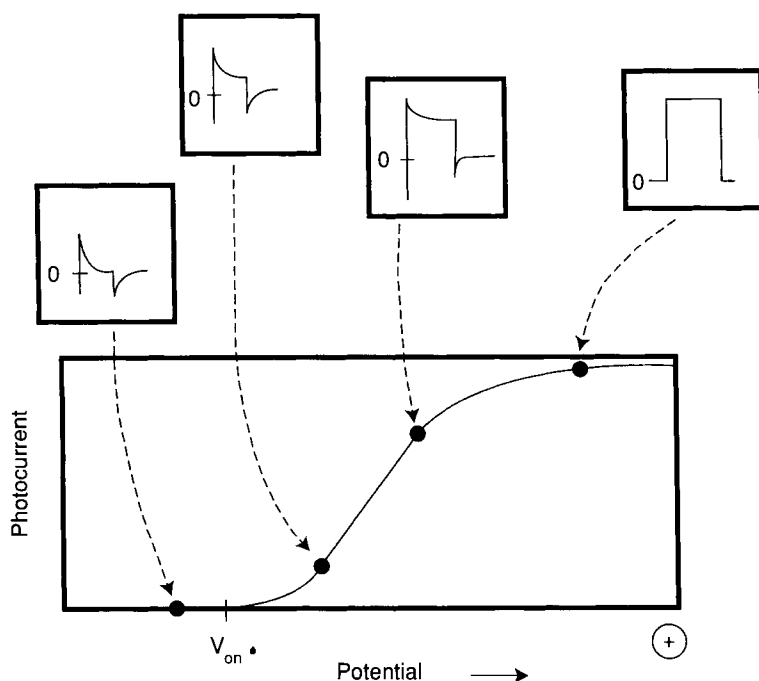

Figure 25. Schematic illustration of the transient profiles that would be seen under interrupted illumination as the potential is slowly scanned in the reverse bias regime. The situation as shown is for an n-type semiconductor–electrolyte interface. V_{on} is the potential for the onset of photoanodic current flow.

At potentials near the photocurrent onset (roughly V_{fb}), a spiked response is seen with a characteristic ‘overshoot’ when the light is turned off. At positive potentials near the plateau regime (again for the specific illustrative case of an n-type semiconductor), the response reverts to a rectangular profile that mimics the excitation waveform. Intermediate response patterns manifest at potentials in between.

The transient behavior in Figure 25 can be rationalized by invoking a surface-state mediated model of the sort shown in Figure 21. Model simulations and experiments have been reported for p-GaP photocathodes in acidic electrolyte [93, 211]. Similar experiments on n-CdSe electrodes have been reported [123].

Perhaps more challenging from both experimental and modeling perspectives is the δ -excitation case. Primary electron–hole pair separation occurs in the sub-nanosecond or picosecond time domain and light pulses with temporal resolution of $\sim 10^{-10}$ s (or better) are required. However, both nanosecond and picosecond light pulses have been employed [110–127] and although the analysis has been mostly confined to the slower (nanosecond) decay regime in the photocurrent (or photovoltage) transients, the rise-time domain has also been analyzed (see, e.g., Ref. [256]).

It appears that the carrier generation process is essentially complete within the picosecond time window; subsequent charging of C_{sc} manifests as a photovoltage that can be measured in the external circuit. If this photoinduced charge is discharged through R_m (strictly $R_m + R_{el}$), an exponential decay should appear with a time constant of τ_{cell} . However, faster photocurrent (or equivalently photopotential) transients have been observed (see, e.g., Figure 26 [113]). This initial decay has been

Figure 26. Transient photocurrent data plotted in semilogarithmic format for n-WSe₂ in 1.0 M KI at -0.30 V (vs. SCE) showing the rapid decay component at short times. (Reproduced with permission from Ref. [113].)

attributed to the flow of majority carriers into the hole-populated surface state(s) [2]. Note that this current flow is opposite in sign to the minority carrier component and accounts for the polarity of the ‘overshoot’ pattern in Figure 25.

The laser coulostatic experiment on semiconductor–electrolyte interfaces, in fact, has an early history dating back to ca. 1980. These and other similar works have been reviewed [2, 3, 9]. Luminescence decay experiments shed light on the competition between charge transfer, nonradiative recombination and luminescence, pathways. Once again, the reader is referred to the aforementioned reviews for further details.

Finally, light-modulated microwave conductivity measurements complement other non-steady-state methods in that when the rate constant for carrier recombination is zero, the photocurrent simply follows the perturbation profile (zero phase change) such that no information about the rate of interfacial charge transfer can be gleaned. On the other hand, light-modulated microwave reflectivity measurements still provide kinetic information at high semiconductor band-bending at the interface. Further details of the advantages and limitations of this technique are available [100–107].

Periodic excitation: the IMPS and PEIS experiments

As mentioned earlier, in these cases either the light intensity (IMPS) or the applied potential (PEIS) is sinusoidally varied. The potential is fixed in the former case and the light intensity is maintained constant in the latter. We shall consider IMPS mainly in what follows; further details and entry into the original literature, can be found elsewhere [2, 9, 10].

In IMPS, the light intensity has both a ‘DC’ and an ‘AC’ component:

$$I(t) = I_{\text{DC}} + I_{\text{AC}} \sin(\omega t) \quad (30)$$

where ω is the angular frequency (in rad s^{-1}). Generally, I_{AC} is chosen to be a small fraction of I_{DC} to insure a linear response. The corresponding Gärtner flux (Eq. 24) also has AC and DC components:

$$J(t) = J_{\text{DC}} + J_{\text{AC}} \sin(\omega t) \quad (31)$$

where J refers to the flux of minority carriers. After some algebra (see, e.g., Refs. [9, 10]), the dimensionless equivalent of Eq. 24 for the IMPS case becomes

$$\Phi(\omega) = \frac{j_{\text{ph}}(\omega)}{e_0 J_{\text{AC}}} = \frac{k'_{\text{et}} + i\omega}{k_{\text{rec}} + k'_{\text{et}} + i\omega} \quad (24a)$$

Note that both the quantum yield and the photocurrent density are a function of the modulation frequency, ω . The k s in Eq. 24a are *first-order* rate constants (with dimensions of s^{-1}) for electron transfer (k'_{et}) and carrier recombination (k_{rec}), respectively. The prime in k'_{et} distinguishes it from its bimolecular (second-order) counterpart discussed earlier (Section 1.5.1).

The complex function embodied in Eq. 24a can be broken down into its real and imaginary components:

$$\text{RE}\left(\frac{j_{\text{ph}}}{e_0 J_{\text{AC}}}\right) = \frac{(k'_{\text{et}} + k_{\text{rec}})k'_{\text{et}} + \omega^2}{(k'_{\text{et}} + k_{\text{rec}})^2 + \omega^2}$$

and

$$\text{IM}\left(\frac{j_{\text{ph}}}{e_0 J_{\text{AC}}}\right) = \frac{k_{\text{rec}}\omega}{(k'_{\text{et}} + k_{\text{rec}})^2 + \omega^2} \quad (32)$$

As with AC impedance spectroscopic data, IMPS data can be displayed in complex plane (Nyquist) format as exemplified by Figure 27.

In the low-frequency limit ($\omega \rightarrow 0$), Eq. 32 collapses to the ratio $k'_{\text{et}}/(k'_{\text{et}} + k_{\text{rec}})$. In the high-frequency limit ($\omega \rightarrow \infty$), Φ is unity (in the absence of RC attenuation effects, see below). The maximum of the semi-circular arc occurs at $\omega_{\text{max}} = k'_{\text{et}} + k_{\text{rec}}$. One of the advantages of IMPS (relative to DC measurements) is that surface recombination can be ‘frozen out’ at the high-frequency limit.

As with the transient measurements discussed earlier, τ_{cell} also sets a limitation on IMPS measurements. It has been shown [257–259] that τ_{cell} gives rise to an additional semi-circle in the positive-negative (fourth) quadrant. Further, if τ_{rec} is comparable to τ_{cell} , the normalized plot will cross the real axis at a point less than unity, unlike in the case in Figure 27a. In these original model simulations [257, 258], it was assumed, as usual, that $C_{\text{H}} \gg C_{\text{sc}}$. The more general case when C_{H} and C_{sc} are of comparable magnitude has been treated more recently [259].

Figure 27b contains representative experimental IMPS plots for the n-InP– H_2SO_4 interface [92]; note that these data are displayed in non-normalized fashion, unlike the simulation in Figure 27a. Rate constants (k_{rec} and k'_{et}) were extracted from these data as was the branching ratio, $k'_{\text{et}}/(k'_{\text{et}} + k_{\text{rec}})$, all as a function of potential [92]. Many other semiconductor–electrolyte interfaces have been studied by IMPS, and Refs. [2], [9], and [10] should be consulted for citations of the original papers.

The relationship between IMPS and PEIS has been discussed by a number of authors [92, 260, 261]. In general, the information content appears to be equivalent.

1.6.5 Hot Carrier Transfer

Short-wavelength photons (of energy much greater than E_{g}) create ‘hot’ carriers. If, somehow, thermalization of these carriers can be avoided, photoelectrochemical reactions that would otherwise be impossible with the ‘cooled’ counterparts, i.e., at very negative potentials for n-type semiconductors, would be an intriguing possibility. The key issue here is whether the rate of electron transfer across the interface can exceed the rate of hot electron cooling. The observation of hot carrier effects at semiconductor–electrolyte interfaces is a controversial matter (see, e.g., Refs. [3],

(a)

(b)

Figure 27. Simulated (a) and experimental (b) IMPS plots in Nyquist format. The latter are shown for the p-InP–1 M H₂SO₄ interface at various bias potentials. (Reproduced with permission from Refs. [10] and [92].)

[7], [11], [86]) and practical difficulties include problems with band-edge movement at the interface and the like [4]. Under certain circumstances (e.g., quantum-well electrodes, oxide film-covered metallic electrodes), it has been claimed that hot carrier transfer can indeed be sustained across the semiconductor–electrolyte interface [7, 262, 263].

1.7 Multi-electron Photoprocesses

Until now we have mainly considered redox electrolytes comprising one-electron oxidizing or reducing agents. Multi-electron redox processes, however, are important in a variety of scenarios. Consider the reduction of protons to H_2 (HER), a technologically important electrochemical process that has also been extensively studied from a mechanistic perspective on metallic electrodes.

Photoelectrolytic processes such as HER can be carried out on semiconductor electrodes. One can envision an HER mechanism on a p-type semiconductor of the following sort:

where S denotes a surface state and both direct (reactions 33c and 33d) and indirect (i.e., surface-state mediated) (reactions 33b and 33e) radical and H_2 generating pathways are shown. Reactions 33g and 33h represent recombination routes involving the reaction intermediates.

Admittedly this scheme is daunting in its complexity and the kinetic implications are as yet unclear. Early studies on p-GaP, p-GaAs and other Group III–V (13–15) semiconductors reported onset of cathodic photocurrents (attributable to HER) only at potentials far removed (ca. 0.6 V) from V_{fb} (see, e.g., Ref. [264]). This was attributed to steps 33b and 33h in the above scheme. More recent work [91] has shown that the HER at illuminated p-InP–electrolyte contacts is accompanied by a photocorrosion reaction, leading to indium formation on the semiconductor surface. Representative PEIS data from this study are shown in complex plane format in Figure 28. Note that unlike in the cases above (e.g., Figure 27), *multiple* relaxa-

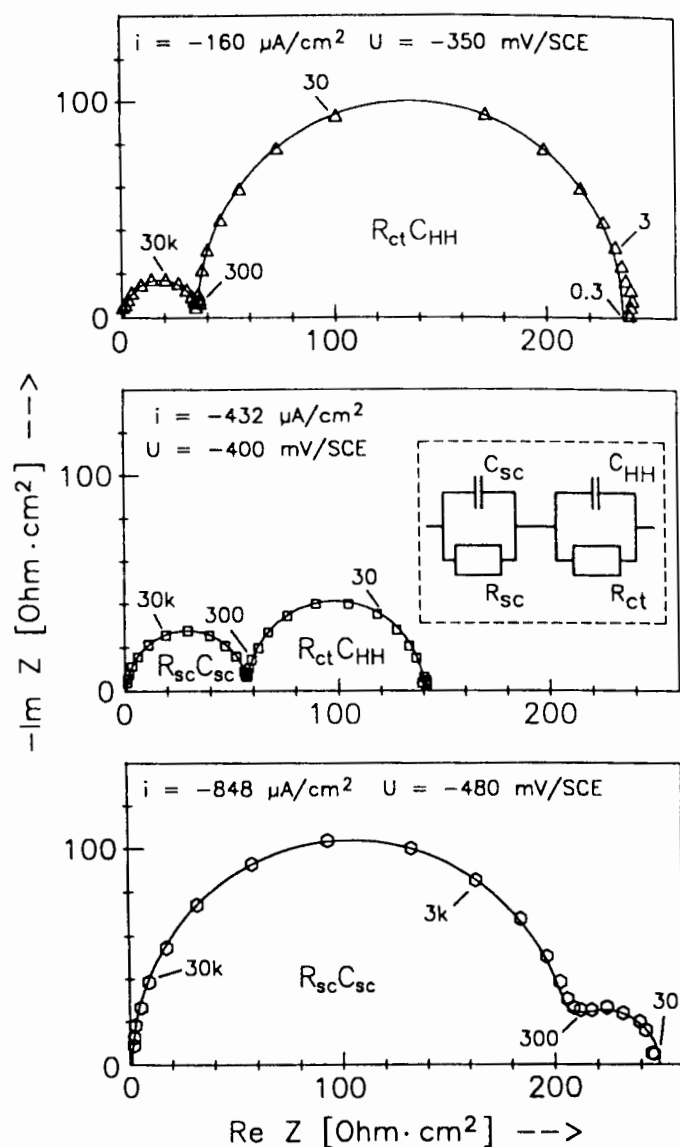

Figure 28. PEIS data for the p-InP-1 M H₂SO₄ interface at a constant illumination intensity and varying photocurrent densities and bias potentials as shown. Both data points and model fits are shown with the equivalent circuit employed shown in the inset. $R_{sc} \equiv R_r$ in our notation (refer to text). (Reproduced with permission from Ref. [91].)

tions are seen that were assigned to $R_r C_{sc}$ and $R_{ct} C_H$ combinations, respectively [91], where R_r is the recombination (diode) resistance (see Section 1.5.2) and R_{ct} is the Faradaic resistance. Multiple arcs are characteristic signatures of multi-electron redox processes, as we shall see soon.

Interestingly, surface states themselves were chemically identified with H^*_{ads} (adsorbed hydrogen atom intermediates) in the aforementioned study [264]. These species have also been implicated in accumulation layer formation and anodic EL at n- and p-GaAs–electrolyte interfaces [265–267].

Another interesting characteristic of many multi-equivalent redox systems is the phenomenon of photocurrent multiplication. This phenomenon may be illustrated for two systems utilizing illuminated n-type and p-type semiconductors:

n-type:

p-type:

Thus, the key feature of photocurrent multiplication is a majority carrier injection step (reaction 34b or 34d) from a reaction intermediate (usually a free radical) into the semiconductor CB or VB, respectively. Thus, in the examples above, each photon generates two carriers in the external circuit, affording a quantum yield (in the ideal case) of 2. This is the ‘current-doubling’ process.

Practically, however, quantum yields somewhat lower than 2 are usually measured because step 34b or 34d competes with the further photooxidation or photo-reduction of these intermediates, respectively. This is true especially at high photon flux values. Even multiplication factors as high as 4 are possible as in the photo-dissolution of n-Si in NH_4F media [268–271].

Photocurrent multiplication has been observed for a variety of semiconductors including Ge [269], Si [268–271], ZnO [272–278], TiO_2 [279–282], CdS [283, 284], GaP [285], InP [286] and GaAs [287–289]. These studies have included both n- and p-type semiconductors, and have spanned a range of substrates, both organic and inorganic. As in the Si case, this phenomenon can also be caused by photo-dissolution reactions involving the semiconductor itself. The earlier studies have mainly employed voltammetry, particularly hydrodynamic voltammetry (see, e.g., Ref. [282]).

As more recent examples (see Refs. [2], [9] and [10] for reviews) reveal, IMPS is a powerful technique for the study of photocurrent multiplication. Unlike in the cases discussed earlier (Figure 27), majority carrier injection leads to a component of the

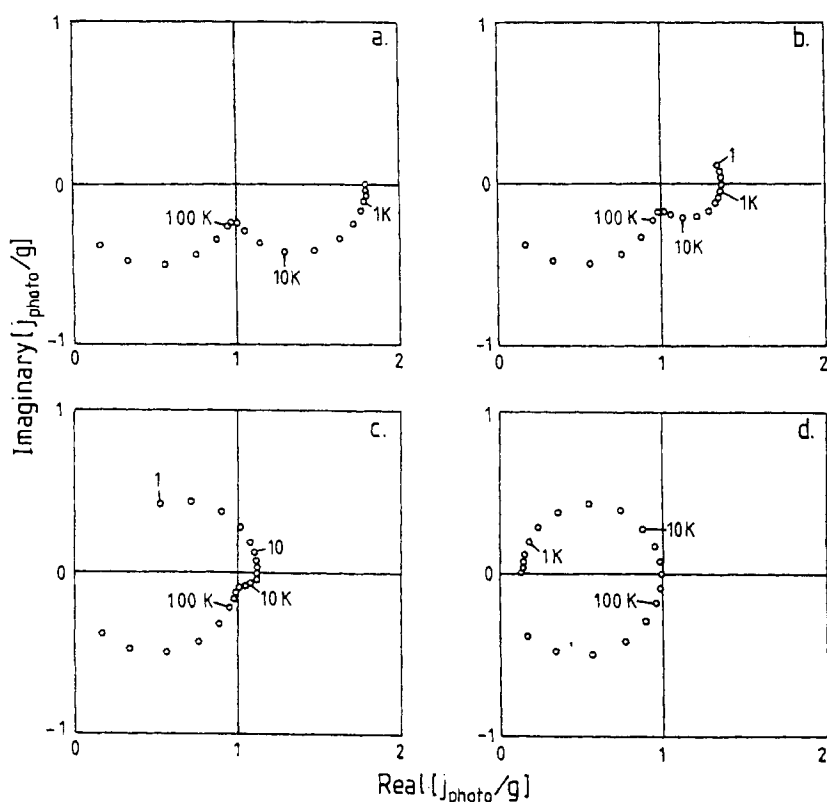

Figure 29. Simulated IMPS plots showing the competition between recombination and current doubling. The IMPS response switches from current doubling control in (a) to recombination control in (d). The band-bending values are 0.40, 0.35, 0.30 and 0.20 eV in (a), (b), (c) and (d) respectively. Refer to the original work for other simulation parameters. (Reproduced with permission from Ref. [284].)

photocurrent flux that lags behind the in-phase component associated with minority carrier processes. As the modulation frequency is increased, this injection component is progressively attenuated. Thus, the complex plane plot (that now lies in the *lower* quadrant) has a low-frequency intercept corresponding to 2 (in the ideal case). The high-frequency intercept tends toward a quantum yield of 1. In the presence of recombination, the plot becomes more complex.

Figure 29 contains a family of simulated IMPS plots showing the competition between recombination and current doubling [284]. At high band bending, the latter controls the response (along with the *RC* attenuation effect discussed in Section 1.6.4). On the other hand, recombination control manifests at 0.2 eV along with the lower-quadrant *RC* effect. Figure 30 contains simulated and experimental IMPS plots for the photodissolution of n-Si in NH_4F [270, 271]. As pointed out earlier,

Figure 30. Experimental and simulated IMPS plots for the photodissolution of n-Si in 1.0 M NH_4F at pH 4.5. (Reproduced with permission from the authors of Ref. [9].)

multiple arcs are seen for the sequential injection of electrons from the dissolution intermediates.

The frequency windows for the study of photocurrent multiplication by IMPS is set by the dynamic response of the potentiostat (at high frequencies) and by the RC time constant attenuation. The injection rate constant, k_{inj} (first-order), can be calculated from the minimum of the arc, ω_{min} ; the upper limit to k_{inj} appears to be ca. 10^5 s^{-1} [9]. For example, k_{inj} for formic acid oxidation on n-CdS has been estimated to be $6 \times 10^4 \text{ s}^{-1}$ [284].

This leads us to another important category of multi-electron photoprocesses involving the semiconductor itself. While photocorrosion is a nuisance from a device operation perspective, it is an important component of a device fabrication sequence in the microelectronics industry. Two types of wet etching of semiconductors can be envisioned [290]. Both occur at open-circuit but one involves the action of chemical agents that cause the simultaneous rupture and formation of bonds. This is exemplified by the action of H_2O_2 on GaAs [291]:

In the first step (1), the oxidant injects a hole into the surface bond between Ga and As. In the second step (2), a second hole is injected and the bond between Ga and As is broken with a new bond formed between As and hydroxyl species.

The second type of wet etching is called electroless etching [290]. This is based on the injection of a hole into the VB (for an n-type semiconductor). This dark process was discussed in some detail in Section 1.5.2.

The formation of an electron-deficient bond (as in reaction 35) can also be instigated by photogenerated holes. It has been shown that the resultant intermediates (especially for Group III–V materials) can act as effective electron traps for CB

electrons in the overall process [292, 293]:

The 'surface state' is thus neutralized and the surface bond is repaired. The $\bullet\text{OH}$ radical can then efficiently inject a VB hole:

The net result is that the surface state is freed for a new reaction cycle to be re-initiated.

An important feature of wet etching is the possibility of changing the dissolution rate *locally* by application of photons with energy larger than E_g . Such photo-etching processes are relevant to several aspects of semiconductor technology including the production of highly anisotropic holes and grooves, specific geometric structures such as gratings and mesas, selective layer removal in heterostructures, and the like. Generically, photoetching can be represented by the following scheme:

A binary compound semiconductor (e.g., GaAs) has been assumed here and reaction 36b underlines the fact that charge neutrality in the system is maintained by reduction of Ox, an added oxidant (e.g., Ce^{4+}). Several aspects of photoetching have been reviewed [70, 166–168], including reaction mechanisms, morphology of the etched surfaces, and etching kinetics in the dark and under illumination. General rules for the design of anisotropic photoetching systems have also been formulated [294].

1.8 Nanocrystalline Semiconductor Films and Size Quantization

1.8.1 Introductory Remarks

From a materials perspective, the field of semiconductor electrochemistry and photoelectrochemistry has evolved from the use of semiconductor single crystals to polycrystalline thin films and, more recently, to nanocrystalline films. The latter have been variously termed membranes, nanoporous or nanophase films, mesoporous films, nanostructured films, etc.; they are all distinguished from their poly-

crystalline electrode predecessors by the crystallite size (nm versus μm in the former) and by their permeability to the electrolyte phase. We shall simply call these films ‘nanocrystalline’ in what follows. The above features render three-dimensional geometry to nanocrystalline films as opposed to the ‘flat’ or two-dimensional (planar) nature of single crystals or polycrystalline counterparts.

What are the virtues of these emerging photoelectrode materials? The first is related to their enormous surface area. Consider that the 3-D structure is built up of close-packed spheres of radius r . Then ignoring the void space, the specific area, A_s (area/volume), is given by $3/r$ [295]. For $r = 10\text{ nm}$, A_s is of the order of 10^6 cm^{-1} and for a 1 cm^2 film of $1\text{ }\mu\text{m}$ thickness, this value corresponds to an *internal* surface area of $\sim 100\text{ cm}^2$ (i.e., a ‘surface roughness factor’ of 100). Clearly, this becomes important if we want the electrolyte redox species to be adsorbed on the electrode surface (see below). Alternatively, a large amount of sensitization dye can be adsorbed on the support semiconductor although this dye sensitization approach is not considered in this chapter. By way of contrast, the amount of species that can be confined in a monolayer on a corresponding flat surface would be negligibly small.

As we shall see later, electron transport in nanocrystalline films is necessarily accompanied by charge-compensating cations because the holes are rapidly injected into the flooded electrolyte phase. This provides opportunities for studying ion transport processes in mesoporous media, that are coupled to electron motion. Ion insertion also has practical consequences as in energy storage device applications [296].

Surface state densities of the order of $\sim 10^{12}\text{ cm}^{-2}$ are commonplace for semiconductor electrodes of the sort considered in previous sections of this chapter. These translate to equivalent volume densities of $\sim 10^{18}\text{ cm}^{-3}$ for nanocrystalline films. Such high densities enhance light absorption by trapped electrons in surface states, giving rise to photochromic and electrochromic effects [297–299] (see below). Unusually high photocurrent quantum yields are also observed with sub-band-gap light with these photoelectrode materials. Corresponding sub-band-gap phenomena are rather weak and difficult to detect with single crystal counterparts.

1.8.2 Preparation of Nanocrystalline Electrode Films

These films can be prepared by a variety of routes, only a few of which are mentioned here. The original references should be consulted for more practical details. Titanium dioxide is used as an illustrative example below. First, colloidal solutions are prepared, e.g., from titanium isopropoxide. The resultant sol is concentrated under vacuum at room temperature until its viscosity increases. Then it is spin-coated on to suitable supports (e.g., conducting glass) and fired in an oven. The firing temperature critically controls the morphology of the resultant film as discussed elsewhere [300–303]. Films up to several micrometers thick can be prepared by this simple version of the sol–gel technology [304]. Aerosol or spray pyrolysis is a somewhat related approach [305, 306].

In another variant of this procedure, the oxide powder itself is used as a precursor. For example, a paste can be generated by grinding this powder with water and

acetylacetone along with other additives (e.g., Triton X-100) [301, 307–308]. The resultant dispersion can be either spread or brush-coated on to the support material. A final sintering at $\sim 400\text{--}450^\circ\text{C}$ in air completes the film preparation sequence.

Electrodeposition [309–311] and chemical bath deposition (CBD) [312, 313] are two other attractive routes for the preparation of nanocrystalline films. Oxides such as ZnO and TiO_2 [314–318] and other Group II–VI (12–16) semiconductors (e.g., CdS, CdSe, CdTe) [319, 320] can be prepared in nanocrystalline form via these routes. Hybrid electrochemical chemical synthesis routes have also been devised [321].

Finally, a single crystal itself provides a template for preparing a highly porous layer on top of it. This photoetch strategy, which was initially used for silicon from a luminescent device perspective [322], has been subsequently employed for enhancing the photoresponse of indirect band-gap semiconductors such as GaP [323, 324]. Interestingly, an early report on porous TiO_2 layers formed by anodization in the dark claimed a higher quantum yield in the long-wavelength regime relative to single-crystal rutile [325]. However, this behavior was ascribed by the authors to the formation of anatase ‘pockets’ in the anodic film or to the incomplete oxidation of the Ti foil that was employed [325].

1.8.3 The Nanocrystalline Film–Electrolyte Interface and Charge Storage Behavior in the Dark

Understanding of the electrostatics across nanocrystalline semiconductor film–electrolyte junctions presents interesting challenges, particularly from a theoretical perspective. Concepts related to space-charge layers, band-bending, flat-band potential and the like (Section 1.3) are not really applicable here because the crystallite dimensions comprising these layers are comparable to (or even smaller than) nominal depletion layer widths.

The fairly complete interpenetration of the electrode and electrolyte phases must mean that the Helmholtz double layer extends throughout the interior surface of the nanoporous network, much like a supercapacitor [9, 326] situation. Finally, unlike in the cases treated earlier, the semiconductor (especially if it is a metal oxide) is not heavily doped such that free majority carriers are not present in appreciable amounts. This is indicated, for example, by the sensitivity of the conductivity of nanocrystalline TiO_2 layers to UV light—the conductivity is strongly enhanced on UV exposure much like a photoconductive effect. This effect has been interpreted in terms of trap filling with recombination times considerably slower than the trapping processes under reverse bias [327, 328]. The light sensitivity also is diagnostic of the fact that the low electronic conductivity in the dark is not due to high inter-particle resistances (i.e., in the ‘neck’ regions), but rather is indicative of the low electron concentrations.

The electron concentration can be increased by forward biasing the nanocrystalline electrode–electrolyte interface potentiostatically. The interface is thus driven into the accumulation regime for the majority carriers and if a transparent rear contact (e.g., F-doped, SnO_2 or Sn-doped indium oxide) is used, the resultant blue

(or bluish black) coloration of the film can be monitored spectroscopically [298, 299, 329]. Whether the optical response arises from conduction band electrons or from electrons trapped in surface states is not entirely clear. It has been claimed [330] that the absorption spectrum of the latter differs significantly from that of conduction band electrons. Electrons in surface states can be chemically identified with Ti^{3+} defect sites that can be detected, for example, by electron paramagnetic resonance spectroscopy [307, 331].

In either case, the resultant negative charge generated by electron accumulation at the internal surfaces has to be balanced by cations (from the electrolyte phase) for charge compensation. Such ion insertion reactions have been studied using techniques such as voltammetry, reflectance or absorption spectroscopy, chronoamperometry and electrochemical quartz-crystal microgravimetry [329, 332–336]. Both aqueous and aprotic electrolytes have been deployed for these studies.

Unlike in the single-crystal cases treated earlier, placement of the semiconductor energy band positions at the interface via Mott–Schottky analyses is not straightforward for nanocrystalline films. Abrupt changes in slope and other nonidealities [307, 337, 338] have been observed, for example, in the Mott–Schottky plots for TiO_2 films and attributed to the influence of the conductive glass that is normally employed to support these films. This behavior is especially prevalent under reverse bias. The onset of majority carrier optical absorption (in the visible and near-IR range) under forward bias instead has been profitably employed to place the conduction band positions of TiO_2 in aqueous media [298].

Impedance spectroscopy and electrochemical dye desorption experiments have been employed [339] to study the electrical characteristics of TiO_2 nanocrystalline films in the dark. This study and the others cited above demonstrate how the conductivity changes (as a result of electron injection from the support electrode) can cause the porous/nanocrystalline layer to manifest itself electrically, such that the active region moves away (i.e., outward) from the support as the forward bias voltage is increased. The potential distribution has also been analyzed depending on whether the depletion layer width exceeds or is smaller than the typical dimension of the structural units in the nanocrystalline network [338].

1.8.4 Photoexcitation and Carrier Collection: Steady-state Behavior

Figure 31 contains a schematic representation of the nanocrystalline semiconductor film–electrolyte interface at equilibrium (Figure 31a) and the corresponding situation under bandgap irradiation of the semiconductor (Figure 31b) [9]. Since the diffusion length of the photogenerated carriers is usually larger than the physical dimensions of the structural units, holes and electrons can reach the impregnated electrolyte phase before they are lost via bulk recombination. This contrasts the situation with the single-crystal cases discussed earlier.

If, as is the case with TiO_2 nanocrystalline films, the holes are rapidly scavenged by the electrolyte redox (specifically Red) species, collection of the photogenerated electrons at the rear contact becomes the determinant factor in the quantum yield. Thus, the quasi-Fermi level for holes remains close to $E_{\text{F, redox}}$ and that for elec-

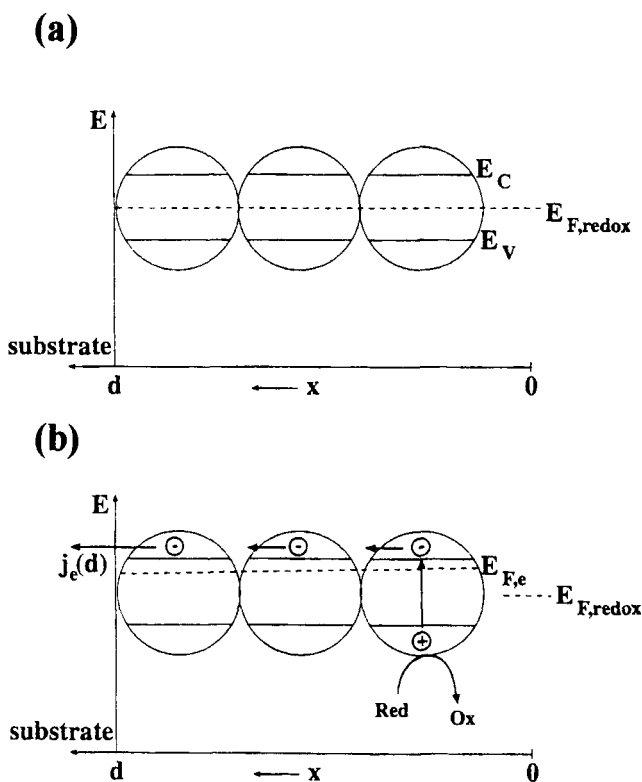

Figure 31. Schematic representation of a nanocrystalline semiconductor–electrolyte interface in the dark (a) and under illumination from the electrolyte side (b). E_c and E_v correspond to E_{CB} and E_{VB} in our notation. (Reproduced with permission from the authors of Ref. [9].)

trons, $E_{F,e}$, moves ‘up’ as depicted in Figure 31b. Illumination thus induces an electron flux, $J_n(x)$ through the nanocrystalline phase. Under steady-state conditions, the photocurrent density (j_{ph}) is equal to $e_0 J_n(x = d)$. The driving force for electron diffusion through the network of nanocrystallites has been calculated from first principles [340]. It has been found that the driving force is ca. kT/e_0 divided by the thickness of the network. Importantly, this free-energy gradient is found to be independent of the incident photon flux.

It is important to reiterate that the charge separation in a nanocrystalline semiconductor–electrolyte interface does not depend on a built-in electric field at the junction as in the single-crystal case. Instead, the differential kinetics for the reactions of photogenerated electrons and holes with electrolyte redox species accounts for the charge separation (and the generated photovoltage). The molecular factor(s) underlying the sluggish scavenging of electrons at the nanocrystalline film–electrolyte boundary (by the redox species) are as yet unclear. Of course, the competition between *surface* recombination of these electrons (with the photogenerated holes) and collection at the rear contact dictates the magnitude of the quantum yield experimentally measured for a particular junction.

Photocurrent losses have been recorded for electrolytes dosed with electron acceptors such as O_2 and iodine [341]. Nanocrystalline TiO_2 electrodes with thick-

nesses ranging from 2 to 38 μm were included in this study. In the presence of the above electron-capture agents, electron collection (i.e., photocurrent) at the rear contact was seriously compromised. On the other hand, as high as 10 % of the photons were converted to current for a 38 μm thick film in an N_2 -purged solution [341].

The above result was obtained with front-side illumination geometry. As one would intuitively expect, carrier collection is most efficient close to the rear contact. Indeed, marked differences have been observed for photoaction spectra with the two irradiation (i.e., through the electrolyte side vs. through the transparent rear contact) geometries for TiO_2 , CdS and CdSe nanocrystalline films [319, 342]. Obviously, the relative magnitudes of the excitation wavelength and the film thickness critically enter into this variant behavior.

In most cases, the iodide–triiodide redox couple has been employed (presumably because of its success in shuttling the photo-oxidized dye in the sensitization experiments) although other redox electrolytes {e.g., $\text{SCN}^-/(\text{SCN})_2^-$, [342]} have also been employed. For the chalcogenide films, sodium selenosulfite was employed [319]. It must be noted that, aside from losses due to the surface recombination and back-reactions, an additional loss component from the increase in film resistance must also be recognized especially as the film thickness is increased. The resistance loss manifests as a deterioration in the photovoltage and fill factor.

In the discussion to this point, we have not considered trapping/release of the photogenerated electrons as they undergo transit to the rear contact. However, electrons trapped in localized interfacial states induce a counter-charge in the Helmholtz double-layer, as discussed in the preceding discussion. The resultant voltage drop can introduce a non-negligible field component into the diffusional process. The time dependence of the electron density, $n(x, t)$, is given by [9]

$$\frac{\partial n(x, t)}{\partial t} = \eta \alpha I_0 e^{-\alpha x} + D_n \frac{\partial^2 n(x, t)}{\partial x^2} - \frac{n(x, t) - n_0}{\tau} \quad (37)$$

where η is the electron injection efficiency, D_n is the diffusion coefficient of electrons and τ is the pseudo-first-order lifetime of electrons determined by back-reaction with Ox.

Even if the migration component is negligible (but see below), solution of Eq. 37 presents difficulties because of the possible dependence of D_n on n and x . Similarly, τ may depend on these two variables also. Nonetheless, the steady-state solution of Eq. 37 has been obtained [343] by assuming that D and τ are constant and that $\eta = 1$. Under these conditions, the photocurrent is predicted to be independent of voltage—a rather physically implausible situation. In the forward bias regime, η is expected to decrease and back-reaction of the photogenerated electrons (with Ox) can no longer be neglected.

This brings us to the rear support–film interface. What sort of barrier exists at this junction? Are the electron exchange kinetics voltage-dependent at this interface? The effect of changing the work function of the substrate on the current–voltage curves (in the dark and under illumination) has been investigated for TiO_2 nanocrystalline films [344]. The onset potential for the photocurrent is found to be the

Figure 32. Photovoltammogram under interrupted illumination of a nanocrystalline CdS–sodium sulfite electrolyte interface in the reverse-bias regime.

same regardless of whether SnO_2 , Au or Pt is used to support the film. A Fermi level pinned *rear* interface was used to explain the results.

In general, the voltammograms for nanocrystalline electrodes are not unlike what is observed for their single-crystal counterparts. An example of a photovoltammogram for CdS is shown in Figure 32. The fact that an S-type profile is observed culminating in a photon flux-limited plateau regime is surprising given that the film is rather insulating and the electrolyte permeates into the network and possibly contacts the rear support electrode. The transition in the profiles from spiked at potentials near V_{on} (photocurrent onset) to more rectangular at positive bias potentials (not shown in Figure 32) must mean that the voltage does exert an effect on carrier transit through the network. No satisfactory explanation appears to exist at present to resolve this apparent anomaly.

1.8.5 Photoexcitation and Carrier Collection: Dynamic Behavior

In this section, we briefly consider the response of nanocrystalline semiconductor–electrolyte interfaces to either pulsed or periodic photoexcitation. Several points are worthy of note in this respect: (a) the photocurrent rise-time in response to an illumination step is nonlinear. Further, the response is *faster* when the light intensity is higher. (b) The decay profiles exhibit features on rather slow time-scales extending up to several seconds. (c) The photocurrent decay transients exhibit a peaking behavior. The time at which this peak occurs varies with the square of the film thickness, d . (d) A similar pattern is also seen in IMPS data where the transit time, τ , is seen to be proportional to d^2 .

Figure 33. Complex plane IMPS plot for a nanocrystalline GaP–acid (pH 1.0) electrolyte with illumination from the electrolyte side. (Reproduced with permission from the authors of Ref. [9].)

The above observations have been interpreted within the framework of two distinct models, one involving trapping/detrapping of the photogenerated electrons [345, 346] and the other based on electron diffusion (or field-assisted diffusion) not attenuated by electron localization [347, 348]. The millisecond transit times also mean that the transit times are very long compared with equilibration of majority carriers in a bulk semiconductor or electron–hole pair separation within the depletion layer of a flat electrode. The slow transport is rationalized by a weak driving force and by invoking percolation effects [338].

It is interesting that the response patterns differ for different nanocrystalline electrodes [338]. For example, while trapping/detrapping effects appear to be relatively unimportant for GaP, the response for TiO₂, especially at low photon fluxes, is governed by electron trapping/detrapping kinetics. This accounts for the faster response at higher photon fluxes (see above).

As with the flat film counterparts, IMPS is also yielding a wealth of dynamic electron transport information for nanocrystalline films [346, 349–352]. An interesting point of contrast with the former is the fact that the imaginary component of the IMPS response is negative over most of the frequency range (Figure 33). In minority carrier processes for a semiconductor–electrolyte interface, on the other hand, the response lies in the upper complex plane (see, e.g., Figure 27). This stems from the fact that the phase delay is negative for majority carrier processes (i.e., there is a phase lag) whereas minority carriers involved in surface recombination ‘lead’ the illumination [9].

A further characteristic IMPS signature for nanocrystalline films is a spiral in the high-frequency regime as exemplified by the complex plane plot in Figure 33 [349]. This spiral is typical of a constant time lag (i.e., frequency-dependent phase shift), and it arises simply from the transit time required for the majority carriers to move

from the front face to the rear contact. In line with this notion, the spiral disappears for rear illumination geometry, i.e., for irradiation through the transparent film contact. The spiral pattern has also been accommodated within a model framework based on field-driven electron transport [349].

Several issues remain to be resolved in studies of electron transport at nanocrystalline semiconductor–electrolyte interfaces. Among these are those related to the variation of excess carrier density with distance (and consequent variations in D and τ across the film), the importance of field-assisted transport phenomena, the role of temporary localization of electrodes in traps, the influence of solution species on transient profiles and the like. However, rapid progress is being made in these directions as exemplified by several published studies [338, 349, 352, 353–355].

1.8.6 Size Quantization

When electronic particles such as electrons and holes are constrained by potential barriers to regions of space that are comparable to or smaller than their de Broglie wavelength, the corresponding allowed energy states become discrete (i.e., quantized) rather than continuous. This manifests in the absorption (or emission) spectra as discrete lines that are reminiscent of atomic (line) transitions; these sharper features often appear superimposed on a broader envelope. Another manifestation for semiconductors is that the energy band-gap (E_g) increases or, equivalently, the absorption threshold exhibits a blue shift. The critical dimension for size quantization (SQ) effects to appear in semiconductors depends on the effective mass (m^*) of the electronic charge carriers. For $m^* \approx 0.05$, the critical dimension is about 300 Å; it decreases approximately linearly with increasing m^* [7].

In general, charge carriers in semiconductors can be confined in one, two or three spatial dimensions, giving rise to quantum wells, quantum wires or quantum particles (or dots). There is much scientific and technological interest in SQ effects in semiconductors. One underlying reason is that the optical, electrical and redox properties of semiconductors can be tuned simply by manipulating their physical dimensions rather than their chemical composition. There is also a fundamental incentive to explore how atomic and molecular properties evolve into bulk ones. Much of this work, particularly that stemming from electrochemical and photochemical perspectives, has been reviewed elsewhere [356–358]. Therefore, in what follows, we merely summarize progress in the preparation of selected nanocrystalline semiconductor films and electrodes exhibiting SQ effects. Several reviews [4, 7, 312, 359] also contain closely related material and should be consulted for further details.

Much of the challenge from a preparation perspective concerns the size distribution of the nanocrystallites within the film. Ideally, this distribution should be as monodisperse as possible. Thus, CBD and electrodeposition have been utilized to prepare films showing SQ effects [312, 360–362]. Even hybrid methods have been employed wherein the chemical and electrodeposition steps are combined [321]. Other strategies to enhance SQ include selection of a particular substrate orientation (e.g., Au[111] planes) [360, 362], host matrix (e.g., clays, Nafion) [363, 364] or

chemically modified support (e.g., silane-functionalized tin oxide) [365, 366]. Techniques such as electrochemical atomic layer epitaxy allow the fabrication of ultra-thin films [367] or multilayered films [368] exhibiting SQ. Of course, molecular beam epitaxy (MBE) and metalloorganic chemical vapor deposition (MOCVD) have long been successfully employed for this purpose by the physics, materials science and engineering communities.

Another interesting photoelectrochemical approach employs selective corrosion or etching of a precursor film to secure SQ. This approach undoubtedly was inspired by the success with the preparation of porous Si (see Section 1.8.2 and Ref. [322]). The idea here is that the energy (or wavelength) of the light that is used for photoetching determines the particle size distribution [369, 370]. Simply put, larger crystallites will preferentially undergo photocorrosion and dissolve away in the medium, leaving behind ultra-small (ångström size) particles exhibiting the SQ effect.

Characterization of these materials presents new challenges. For example, the amounts of ‘active’ material in the film are extremely small, challenging the analytical sensitivity of many common optical absorption techniques. Optical interference from the (highly reflecting) supports (e.g., Au) can be a serious problem. Vibrational spectroscopy of ultra-thin overlayers, although highly desirable for probing SQ effects, demands even higher sensitivity (relative to the UV–visible spectral range) because of the inherently weaker transitions. Nonetheless, a battery of in situ measurement probes have been deployed for studying SQ effects in semiconductor nanocrystalline films. These include photocurrent spectroscopy [362], scanning probe microscopic methods such as AFM and STM [371], photoluminescence [321, 368], resonance Raman spectroscopy [372] and surface-enhanced Raman scattering [367].

The semiconductors in these studies also span a wide range and include CdS, CdSe, ZnO, Fe₂O₃ and TiO₂.

1.9 Charge Transfer Across Chemically Modified Semiconductor–Electrolyte Interfaces

1.9.1 Single Crystals

Much of the research in the early 1980s on chemically modified semiconductor–electrolyte interfaces was directed toward protecting them from photocorrosion; this body of work has been reviewed [373]. Parallel efforts also went into improving minority carrier transfer at the interface by chemisorbing metal ions such as Ru³⁺ on the semiconductor surface. Chemical agents such as sulfide ions are known to passivate the semiconductor against surface recombination [6]. A study [374] on electron transfer dynamics at p-GaAs–acetonitrile interfaces where the semiconductor surface was sulfide-passivated exemplifies this fact. In general, the mechanistic issue of whether the above chemical agents improve minority carrier charge

transfer by minimizing surface recombination or by a true catalytic action has not been completely resolved [1].

Yet another tactic involves perturbing the electrostatics at the semiconductor–electrolyte interface by adsorbing (or even chemically attaching) electron donors or acceptors on the semiconductor surface. In favorable cases, this increases the band-bending at the interface by thus introducing a fixed counter-charge of opposite polarity (negative for an n-type semiconductor) at the junction. Chloride ion adsorption on the n-GaAs surface from ambient-temperature AlCl_3 –*n*-butylpyridinium chloride melts [30, 375] is a case in point; this process serves to improve the junction and the photovoltage that it delivers. Of course, such ‘fixed-charge’ effects have long been known to the solid-state device physics and gas-phase catalysis communities. Other agents that have been deployed for chemical tuning of the interfacial energetics at the semiconductor–electrolyte interface are listed in Table 3.

Table 3. A summary of approaches^a to chemical modification of semiconductor–electrolyte interfaces.

Modification agent(s)	Semiconductor(s)	Modification objective ^b	Sample reference(s)
Ru^{3+}	n-GaAs	A	377, 378
Co^{3+}	n-GaAs	A	379
Os^{3+}	n-GaAs	A	379
Ag^+	p-InP	A	380
S^{2-}	p-GaAs	A	374
HS^-	CdS, CdSe	B	381
Thiolates	CdS, CdSe	B	382
Dithiocarbamate	CdS, CdSe	B	383, 384
Lewis acids	CdS, CdSe	B	385, 386
Lewis bases	CdS, CdSe	B	387
Cl^-	n-GaAs	B	30, 375
Benzoic acid derivatives	n^+ -GaAs	B	376
Noble metals	n- TiO_2	C	388
Noble metals	p-InP	C	377, 389–391
RuO_2^c	n-CdS	C	392, 393
RuO_2^c	n-Si	C	394
Pt^c	p-Si	C	394, 395
Pt^c	n-CdS	C	396
Noble metals	n-CdS	C	391
Noble metals ^d	p-InP	C	397

^a Approaches to photoanode stabilization based on polymer films containing redox functionalities have been reviewed elsewhere, e.g., Refs. [6, 373].

^b (A) minority carrier transfer catalysis and/or surface state passivation; (B) electrostatic modification; (C) catalysis of multi-electron photoprocesses (refer to text).

^c In these cases, the semiconductor electrode also contained a coating, either polymeric or indium tin oxide.

^d The chemically modified photocathode was used in conjunction with n-MoSe₂ (or n-WSe₂) in a two-photoelectrode cell configuration.

Native semiconductor surfaces are fairly inactive from a catalysis perspective. Thus, noble metal or metal oxide islands have been implanted on photoelectrode surfaces as electron storage centers to drive multi-electron redox processes such as HER, photo-oxidation of H_2O and photo-oxidation of HCl , HBr or HI . Examples of this sort of chemical modification strategy are also given in Table 3.

The advent of self-assembled monolayer (SAM) films on electrode surfaces has rendered a high degree of molecular order and predictability to the chemical modification approach. In particular, the use of these insulating, molecular spacers allows the interrogation of critical issues in electron transfer such as the influence of chemical bonding and distance between the support electrode and the redox moieties on the rate constant for electron transfer. Many such studies on gold-confined SAMs have appeared recently [398–400]. Corresponding studies on *semiconductor* surfaces (particularly Group II–V compounds such as GaAs and InP [401–403] and elemental semiconductors such as Si [404]) have also begun to appear.

Alkanethiol-based or alkylsiloxane-based SAMs have been profitably employed in all these instances to probe the distance effect in electron-transfer dynamics. The thiol-based SAMs have the virtue that the spacer length can be predictably altered simply by varying the number of methylene units in the chain. The distance dependence of k_{et} is embodied in the parameter β , the decay coefficient (for a critical discussion of the subtleties involved in the extraction and interpretation of this parameter, see Ref. [399]). A value of 0.49 ± 0.07 has been reported for β for n-InP–alkanethiol–ferrocyanide interfaces [403]. This value is smaller than its counterpart for corresponding films on gold surfaces which range from ~ 0.6 to 1.1 per methylene unit. The reason for this difference is not entirely clear, although several hypotheses were advanced by the authors [403].

1.9.2 Nanocrystalline Semiconductor Films and Composites

Dye sensitization of nanocrystalline semiconductor films certainly represents one popular approach to chemical modification of the interface. However, this topic is covered in detail elsewhere in this series of volumes. Other examples, from a non-dye sensitization perspective, are less common but two recent studies are noted [405, 406]. One utilizes the surface affinity of TiO_2 toward suitably derivatized viologens to construct chemically modified nanocrystalline films suitable for displays, electrochromic (smart) windows, sensors and the like [405]. In the other study [406], the TiO_2 film surface was modified with phosphotungstic acid (PWA). This compound belongs to a family of polyoxometallates that exhibit interesting electron- and proton-transfer/storage properties and also high thermal stability [407]. Hence these modified films would be applicable in areas such as catalysis, sensors, electronics and even medicine.

These TiO_2 –PWA films represent a logical bridge connecting single-phase semiconductor films and multi-component composite systems. Of course, highly evolved multi-component assemblies occur in nature and there is no better example than the plant photosynthetic system. The plant photosynthetic architecture contains synergistic components (e.g., light-harvesting antennae, membranes) each with a well-

defined and complementary function, to convert the incident photon energy, to move electrons vectorially and to store the reaction products. The design and implementation of artificial analogs have proved to be a daunting task, from both synthetic and characterization perspectives. This topic is covered elsewhere in this series of volumes, but we briefly discuss here some simple multi-component assemblies based on semiconductors.

Early examples in the 1980s were aimed at the design of composite systems for photoelectrolytic generation of H_2 . Thus, Nafion and SiO_2 were used as supports for coprecipitated ZnS and CdS for photoassisted HER from aqueous sulfide media [407]. Subsequent work has addressed the mechanistic role of the support in the photoassisted HER [408]. Vectorial electron transfer was demonstrated in bipolar TiO_2 -Pt or CdSe-CoS photoelectrode panels arranged in series arrays for the photodecomposition of water to H_2 and O_2 [409, 410].

More recently, matrix-semiconductor composites, i.e., films comprising of semiconductor particles that are dispersed in a nonphotoactive continuous matrix, have been developed. Examples of matrix candidates are metals and polymers [411–416]. Occlusion electrosynthesis is a versatile method for preparing such composite films, as exemplified by the Ni- TiO_2 and Ni-CdS family [417–419].

Matrix-semiconductor composite films have two virtues from a photoelectrochemical perspective. First, their components can be separately chosen and optimized for a specific function. Thus, the matrix component can be chosen to have good adsorption tendency toward a targeted substrate. The semiconductor component then functions in the role of photogenerating charge carriers either for reducing or oxidizing this sequestered substrate. This photocatalytic strategy has been recently demonstrated both for an organic substrate (formate ion) [420] and an inorganic substrate (sulfite) [421]. The net result in either case is an enhanced photocatalytic performance of the composite because of the high *local* concentration of the substrate resulting from the matrix adsorption process. In principle, high surface area supports of the sort that are normally used in the gas-phase catalysis community can also be used in conjunction with TiO_2 [422, 423]. These would include materials such as Al_2O_3 , SiO_2 and diatomaceous earth. The resultant composite films, however, cannot be used as electrodes because of their poor electronic conductivity.

The second important feature of a metal-semiconductor composite approach is that the metal can function as a template for chemical or electrochemical derivatization to afford a film comprising of molecular redox-semiconductor (or even semiconductor-semiconductor) contacts. Figure 34 generically illustrates the occlusion electrosynthesis approach for preparing M- TiO_2 composite films and a subsequent derivatization with ferri/ferrocyanide to afford the corresponding metal hexacyanoferrate (MHCF)- TiO_2 counterparts [424].

Such an approach was utilized for preparing NiHCF- TiO_2 [424–426] and CuHCF- TiO_2 [424] composites. These films have interesting photoelectrochromic and photoelectrochemical properties. For example, depending on the method of preparation, NiHCF- TiO_2 films exhibit different photoelectrochemical profiles (Figure 35). In the 'normal' case (Figure 35a), little photoactivity is evident at potentials up to the $Fe(II) \rightarrow Fe(III)$ redox point (ca. 0.4 V). Thereafter, photoanodic currents are observed as the photogenerated holes in TiO_2 oxidize the NiHCF(II)

Figure 34. Schematic illustration of the occlusion electrosynthesis approach for the preparation of M-TiO_2 ($\text{M} = \text{metal}$) composite films and subsequent chemical derivatization to yield the metal hexacyanoferrate (MHCF)- TiO_2 counterparts. Refer to the text for further details.

redox centers. The electrons flow into the Ni phase and thence on to the rear Au contact.

On the other hand, in type II films (see inset in Figure 35b), the TiO_2 particles are not in electronic communication with the Ni phase. Hence *photocathodic* current flow is observed under light as the photogenerated electrons in TiO_2 flow into the electrolyte while the holes move into the NiHCF phase and ultimately into the Au contact (Figure 35b). That is, the carrier transit direction is reversed relative to the type I film case in Figure 35a.

Figure 35. Photovoltammograms for NiHCF-TiO₂ composite films prepared by two variant routes (see Ref. [426]). The corresponding composite film architectures are shown schematically as insets.

As the potential is further increased, the Fe(II) redox centers in NiHCF are *electrochemically* oxidized. Now the photogenerated electrons (in TiO₂) can flow into the NiHCF phase and reduce the Fe(III) redox centers thus generated, whereas the holes flow into the electrolyte. In other words, the behavior reverts to the ‘normal’ carrier transit direction for an n-type semiconductor.

Such ‘bipolar’ photoelectrochemical behavior is not commonplace. It has been observed under certain conditions for nanocrystalline CdSe films [319]. Behavior of the sort shown in Figure 35b represents another type of APE (Section 1.6.3) and underlines the fact that the photoelectrochemical behavior of these types of films is dictated by differential electron and hole transfer kinetics rather than by factors related to band-bending as in semiconductor single crystals.

1.10 Concluding Remarks

The foregoing account hopefully illustrates the fact that the fields of semiconductor electrochemistry and photoelectrochemistry remain healthy and vibrant. Much progress has been made in our understanding of charge transfer across semiconductor–electrolyte interfaces, and the pace of research activity does not appear to have abated in the 1990s. In this author’s crystal ball, several profitable avenues will continue to be further explored in the future: chemically modified layers and their influence on charge transfer, nanocrystalline semiconductor films and semiconductor-based composite electrode assemblies. Concurrently, interfacial characterization probes will continue to improve, in terms of both sensitivity and time/space resolution, and new experimental and theoretical tools will also emerge. Indeed, it appears that this field is poised for exciting times ahead.

Acknowledgments

Research in the author’s laboratory on semiconductor electrochemistry and photoelectrochemistry since 1995 is funded, in part, by the Office of Basic Energy Sciences, US Department of Energy. A number of talented and dedicated co-workers and colleagues have been involved in collaborative research with the author over the past 20 years; their names appear in the publications cited from this laboratory. I also thank the University of Texas at Arlington for providing the facilities and infrastructure. My attempts to provide an updated account was facilitated by the receipt of reprints and preprints and many enjoyable discussions with my colleagues in this field. They include: Drs. S. W. Feldberg, D. Fitzmaurice, A. Fujishima, W. P. Gomes, A. Hagfeldt, A. Heller, J. T. Hupp, C. Koval, D. Lincot, S.-E. Lindquist, Y. Nakato, A. J. Nozik, L. M. Peter, K. Uosaki, D. Vanmaekelbergh, D. H. Waldeck and H. Yoneyama. Last but not least, I thank Ms. Gloria Madden for assistance with the preparation of this chapter. Finally, my thanks are due to the Part Editor,

Dr. T. E. Mallouk, for inviting me to undertake this project—while daunting at the outset, it turned out to be an enjoyable and stimulating experience after all!

2 Dye Sensitization of Electrodes

Ping Qu and Gerald J. Meyer

2.1 Dye Sensitization of Planar Electrodes

Sensitization of electrodes can be defined as the process by which interfacial electron transfers occurs as a result of selective light absorption by an entity called a *photosensitizer*, or simply a *sensitizer* [1]. The most common types of sensitizers are organic chromophores and inorganic coordination compounds, generically referred to as dyes. Interfacial electron transfer produces current or voltage response that can be measured in an external circuit. Thus sensitization provides a method for the conversion of a photon into an electrical signal that can be controlled at the molecular level.

The sensitization of electrodes to visible light by dye molecules is an old area of science with a rich history [2]. A dye-sensitized photoeffect was measured at a semiconductor surface as early as 1887 in Vienna [3]. The accepted mechanisms for the dye sensitization of electrodes emerged from photoelectrochemical studies in the 1960s and 1970s [4–6]. These studies were motivated by a desire to quantify interfacial electron transfer processes and develop cells useful for solar energy conversion. The two most common approaches are shown schematically in Figure 1.

The right-hand side depicts a simplified *photoelectrosynthetic cell*. This cell produces both electrical power and chemical products. Many of the early dye-sensitized cells were designed to operate in the manner shown with the goal of splitting water into hydrogen and oxygen. An excited sensitizer, S^* , injects an electron into the electrode and oxidizes a substrate in solution. The injected electron passes through an external circuit and returns to the counter electrode where it reduces another substrate. Shown on the left-hand side is a *regenerative cell* that converts light into electricity with no net chemistry. Dye-sensitized regenerative solar cells have recently achieved remarkably high solar energy conversion efficiencies that have renewed interest in this field. This is subject of Section 2.2. In the regenerative solar cell shown, the oxidation reactions that take place at the photoanode are reversed at the dark cathode.

Figure 1. Schematic representation of regenerative and photoelectrosynthetic cells. S^* is the sensitizer excited state, D is an electron donor, and D^+ is the oxidized electron donor. Regenerative cells convert light into electricity while photoelectrosynthetic cells convert light into electricity and also produce chemical products.

In the remainder of this section we briefly overview fundamental concepts, vocabulary, photoelectrochemical characterization techniques and the dye-sensitization mechanisms developed for planar electrodes. We end the section with a short literature review of dye-sensitization studies.

2.1.1 Thermodynamics and Sensitization Mechanisms

Sensitization of electrodes to light relies on the fact that an excited state is simultaneously a stronger oxidant and a stronger reductant than is the ground state. Knowledge of the sensitizer's formal reduction potentials relative to the energy levels of the conductive substrate allows a priori determination of the direction of current flow and the sensitization mechanism. It is therefore of considerable interest to quantify the energetics of the sensitizer and the electrode with respect to one another. This can be accomplished, at least in principle, by spectroscopic and/or electrochemical measurements as described below.

Sensitizers

The formal reduction potentials, E° , for a sensitizer, S , that are most relevant to dye sensitization correspond to the ground, reduced and excited states. The first two can be directly measured by electrochemical techniques, such as cyclic voltammetry, and often in situ at the sensitized electrode of interest [7]. The excited state reduc-

tion and oxidation potentials of the thermally equilibrated, or thexi state are given by Eqs. 1 and 2 [8]:

$$E^{\circ}(S^{+}/*) = E^{\circ}(S^{+}/0) - \Delta G_{\text{es}} \quad (1)$$

$$E^{\circ}(S^{*}/-) = E^{\circ}(S^{0}/-) + \Delta G_{\text{es}} \quad (2)$$

where ΔG_{es} is the free energy stored in the thermally equilibrated excited state. ΔG_{es} can usually be estimated from the corrected photoluminescence (PL) spectra and is often equivalent to the E_{00} energy, the energy separation between the lowest vibrational levels of the excited state and the ground states. If the excited state is non-emissive, such as an organic triplet state, the free energy may be estimated from quenching studies with known triplet energies or by alternative techniques discussed elsewhere [9, 10].

It is generally assumed that vibrational relaxation occurs prior to interfacial electron transfer and therefore the energetics of the thexi states calculated through Eq. 1 or 2 are relevant [4]. This assumption is almost certainly valid when sensitization involves diffusional approach of an excited state to a conductive interface. However, when the sensitizer is proximate to the electrode surface, rapid interfacial electron transfer from 'hot' vibrational excited states may occur prior to and/or in competition with relaxation to the thexi state. The corresponding potentials of the excited state produced immediately upon light absorption, the Franck–Condon state, can be estimated by replacing ΔG_{es} in Eqs. 1 and 2 with the energy of the excitation light, $h\nu_{\text{ex}}$.

Metals

For metal electrodes, the Fermi level is embedded within a broad distribution of closely spaced electronic levels. The Fermi level describes the occupancy of energy levels of a system at equilibrium and can simply be thought of as the chemical potential of electrons in the solid [10]. When employed in the Fermi–Dirac distribution function, Eq. 3 results:

$$f(E) = [1 + \exp(E - E_{\text{F}})/kT]^{-1} \quad (3)$$

where k is Boltzmann's constant and $f(E)$ gives the occupation probability for an energy level E at an absolute temperature T [10]. Substitution of E_{F} for E demonstrates that the probability of occupation for an energy level at E_{F} at equilibrium is 0.5. For metal electrodes employed in a photoelectrochemical cells, an external bias allows E_{F} to be continuously tuned within the electrochemical window of the cell [7]. It is reasonable to assume that all states below E_{F} are filled and all those above are unfilled.

Semiconductors

Detailed descriptions of semiconductor terminology and photoelectrochemistry can be found in the previous chapter by Rajeshwar. Below are the basic concepts most relevant to dye sensitization followed by a description of sensitization mechanisms.

Terminology

Semiconductors are characterized by a forbidden energy gap, E_g , (band-gap) between the valence band (VB) maximum, E_{VB} , and the conduction band (CB) minimum, E_{CB} . The magnitude of the band-gap is what differentiates semiconductors from insulators: semiconductors have smaller band-gaps (<4 eV) than do insulators. Semiconductors are termed n-type if the majority charge carriers are electrons in the conduction band and p-type if the majority carriers are holes in the valence band. The Fermi level for most pure or intrinsic semiconductors lies near the middle of the band-gap [12]. The effect of doping is to shift the Fermi level closer to E_{CB} for n-type semiconductors and closer to E_{VB} for p-type semiconductors. For moderate dopant levels near room temperature this can be expressed quantitatively by Eqs. 4 and 5:

$$E_F = E_{CB} - kT \ln(N_C/N_D) \quad (4)$$

$$E_F = E_{VB} + kT \ln(N_V/N_A) \quad (5)$$

for n-type semiconductors and p-type semiconductors, respectively, where N_D and N_A are the concentration of donor and acceptor impurities, respectively, and N_C and N_V are the effective densities of states for the conduction band and valence band, respectively.

The two semiconductor potential distribution conditions most relevant to dye sensitization of planar n-type semiconductors are shown schematically in Figure 2. The flat band-condition applies to the case where the band edges are flat right up to the solution interface (Figure 2a). Under ideal conditions, a positive applied potential does not alter the energetic position of the bands at the semiconductor–

Figure 2. Three semiconductor potential distribution conditions for an n-type semiconductor: a) flat band condition, b) depletion condition, and c) depletion condition with Fermi-level pinning.

electrolyte interface. Instead an electric field that extends some distance W into the solid is produced as indicated by the bent bands (Figure 2b). The surface electric field (or space-charge region) thickness of a planar semiconductor is given by Eq. 6 in the Mott–Schottky approximation:

$$W = (2\epsilon\epsilon_0 V_b/qN_D)^{1/2} \quad (6)$$

where ϵ_0 is the permittivity of free space, ϵ is the dielectric constant of the semiconductor, q is the electronic charge and V_b is the amount of band bending [12]. Note that $W \propto (N_D)^{1/2}$, so highly doped semiconductors have thinner depletion layers than do more lightly doped materials at the same V_b .

Many semiconductor–electrolyte junctions do not behave ideally with respect to applied potential. When a high density of surface states exist within the forbidden energy gap, band edge movement (termed Fermi-level pinning or band edge unpinning) may be observed. Under these conditions the semiconductor appears to be metal-like (Figure 2c), and virtually all of the applied potential drops at the semiconductor–sensitizer interface rather than in the semiconductor space-charge layer. Surface states are created by oxide formation, dangling bonds or impurities, or they may be intrinsic to the semiconductor. Fermi-level pinning is common in the more covalent semiconductors and in highly doped, or degenerate, n-type semiconductors where E_F is within the CB continuum [12, 13].

Determination of band edge positions

Capacitance measurements are generally regarded as the most reliable method for determination of the band edge positions at a sensitized semiconductor–electrolyte interface [14]. The Mott–Schottky relationship, Eq. 7:

$$\frac{1}{C^2} = \frac{2}{\epsilon\epsilon_0 q N_D A^2} \left(V - V_{FB} - \frac{kT}{E} \right) \quad (7)$$

describes the dependence of the space-charge capacitance upon the corresponding electric field, where C is the capacitance and A is the electrode area. The intercept of the plot of $1/C^2$ versus applied potentials yields the flat-band potential from which the band edges can be determined if the band-gap and dopant levels are known.

The assumptions in the Mott–Schottky treatment of capacitance data have been discussed in detail elsewhere [15]. Capacitance measurements are performed in the dark in the absence of sensitizers. Any shift in the band edges that might occur with sensitizer adsorption or illumination is therefore unaccounted for in this analysis. Shifts in the band edge positions are known to occur under a variety of conditions, such as (1) specific ion adsorption, (2) trapping of photogenerated carriers and (3) changes in surface state occupation with applied potential [15]. The first of the three conditions has been exploited in dye sensitization of metal oxide semiconductors where the band edge positions shift 59 mV per pH unit through proton adsorption/desorption equilibria. The estimated positions of the band edges in pH 1 aqueous solution for semiconductors relevant to sensitization are shown.

Figure 3. Semiconductor band edge positions vs NHE in pH = 1 aqueous solution.

When presenting a collection of band edge positions such as that shown in Figure 3, it is worth emphasizing that flat-band potentials, from which the band positions are calculated with Eq. 4 or 5, are *not* singular parameters. Under different experimental conditions the flat-band potential will shift. Furthermore, a flat-band potential for a specific electrode determined in situ by extrapolation from deep depletion (such as Mott–Schottky analysis), does not imply that the band edges will remain fixed as the Fermi level of the electrode is raised. Determination of the band edge positions relative to the sensitizers, as discussed further below, is necessary for comparison of experimental data with even the simplest interfacial electron transfer theory. The evaluation of the band edge positions under experimentally meaningful conditions represents a considerable experimental challenge in dye sensitization studies.

Sensitization mechanisms

Gerischer diagrams

Sensitization and interfacial electron transfer mechanisms have been described by Gerischer [4–6]. A basic assumption is that electron transfer, like light absorption, occurs under the restriction of the Franck–Condon principle. The time-scale for interfacial electron transfer is much shorter than that for nuclear motion. This means that the energy terms for electron transfer are different from the thermodynamic formal reduction potentials described above. Gerischer considered the appropriate energy levels and derived a distribution of energy levels when the sensi-

tizer behaves as an electron donor or as an electron acceptor, $W_{\text{don}}(E)$ and $W_{\text{acc}}(E)$ respectively. The distribution results from thermal fluctuations that, when treated classically, give rise to a Gaussian distribution function, Eqs. 8 and 9:

$$W_{\text{don}}(E) = A \exp \left[-\frac{(E - E^\circ)^2}{4kT\lambda} \right] \quad (8)$$

$$W_{\text{acc}}(E) = A \exp \left[-\frac{(E + E^\circ)^2}{4kT\lambda} \right] \quad (9)$$

where k is the Boltzmann constant, λ is the total reorganization energy for electron transfer and T is the absolute temperature. The reorganization energy, λ , contains terms from the sensitizer, the electrode and the solution. Interpretations of the pre-exponential term A have been discussed in the literature [16].

Gerischer's distribution curves can be interpreted as representing the energy dependence of the electron transfer rate constants involving the reduced and oxidized species. Only a few electrochemical studies have attempted to evaluate the model and quantify the distributions and reorganizational parameters [17, 18]. Nevertheless, it has become common practice to draw a pictorial representation of the distributions when discussing interfacial electron transfer kinetics relevant to dye sensitization.

In Gerischer diagrams, the interface is drawn as a perpendicular line with the electrode density of occupied and unoccupied states on the left and Gerischer's distributions for the sensitizer on the right. An example is shown in Figure 4 where the electrode density of states is not included. At first glance, Gerischer diagrams are confusing as there appear to be too many distributions. One must keep in mind that at least two different redox couples are involved, in the case shown a ground state and an excited state, each of which has its own λ and E° . In most literature diagrams, λ is assumed to be approximately the same for the ground and excited states and values between 0.8 and 2.0 eV are typical [19].

According to Gerischer, the simplest description for the rate of electron transfer, r , is given by Eq. 10:

$$r \sim \int \kappa(E) \cdot D_{\text{don}}(E) \cdot D_{\text{acc}}(E) dE \quad (10)$$

with the product of the transfer frequency, κ , the density of occupied and unoccupied electronic states, D_{don} and D_{acc} , and integrated overall energies, E [4]. For adiabatic electron transfer the maximum rate is controlled by the transfer frequency and is typically in the region of 10^{12} s^{-1} . In the cases of strong electronic coupling, nonadiabatic electron transfer is possible at much faster rates. When invoked in dye-sensitized electrode studies, non-adiabatic electron transfer is usually described by Fermi's golden rule.

Equation 10 represents a simple relation useful for predicting interfacial electron transfer rates relevant to dye sensitization. At this time more detailed descriptions

Figure 4. A Gerischer's diagram for a sensitizer, S^0 , and its excited state, S^* .

that account for the molecular details of the specific dye-sensitized electrode assembly are not available. In principle, Eq. 10 also provides an opportunity for experimental rates to be contrasted with theory. In practice, this is rarely done. The overlap of the sensitizer and semiconductor energy levels is critical for determining interfacial electron transfer rate constants and the experimental uncertainty in doing this is significant. This fact has prohibited extensive application of Eq. 10 to real dye-sensitized photoelectrochemical systems. The few cases where Gerischer theory has been successfully applied and tested involve changing only the solution pH while keeping all other variable constant. These studies are described in Section 2.2.2.

Metal sensitization

There are two possible excited state interfacial electron transfer processes that can occur from a molecular excited state, S^* , created at a metal surface: (a) the metal accepts an electron from S^* to form S^{+} ; or (b) the metal donates an electron to S^* to form S^{-} . Neither of these processes has been directly observed. The two processes would be competitive and unless there is some preference, no net charge will cross the interface. In order to obtain a steady-state photoelectrochemical response, back interfacial electron transfer reactions of S^{+} (or S^{-}) to yield ground-state products must also be eliminated. Energy transfer from an excited sensitizer to the metal is thermodynamically favorable and allowed by both Forster and Dexter mechanisms [20, 21]. There exists a theoretical [20] and experimental [21] literature describing 'energy transfer' quenching of molecular excited states by metals. How-

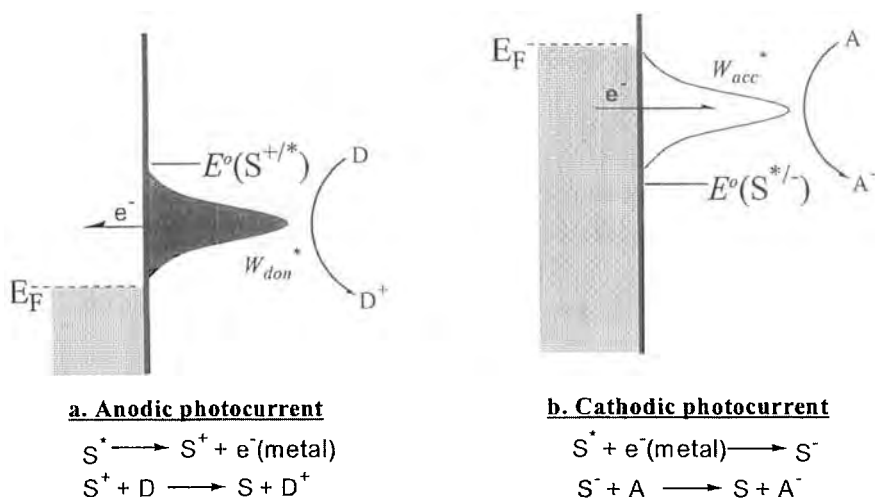

Figure 5. Excited state interfacial electron transfer reactions that can lead to a) anodic, and b) cathodic photocurrent at a metal surface in the presence of electron donor D and acceptor A respectively.

ever, these studies involve photoluminescence measurements and the actual quenching mechanism, electron or energy transfer, remains speculative. Nevertheless, competitive energy transfer quenching is often invoked to rationalize the low photocurrent efficiencies measured at sensitized metallic interfaces. However, there are many reasons to predict poor sensitization yields from metal electrodes [4].

The addition of electron donors or acceptors to the external electrolyte has allowed sustained photocurrents to be measured at sensitized metal interfaces, but the mechanism(s) often remain speculative. A photocurrent can be generated by excited state interfacial electron transfer like that shown in Figure 5, or by intermolecular excited state electron transfer followed by dark redox reactions at the electrode. It can be experimentally difficult to distinguish between these distinct mechanisms and strong evidence exists only for the latter pathway which forms the basis of the photogalvanic cell.

The celebrated 'photogalvanic cells' were the hallmark solar energy conversion devices of the 1940s and 1950s, and continue to be of interest [22, 23]. The cells generally contain a membrane or surface layer that serves to separate two dark metal electrodes and photogenerated redox equivalents. A simple regenerative cell arrangement is shown in Figure 6 with sensitizers embedded in a membrane that allows ion and charge transfer, yet physically separates electron donors, D, and acceptors, A. Clearly, this type of geometric arrangement precludes direct excited state electron transfer with the electrodes. A transmembrane Nernst potential can be generated by photodriven electron transfer occurring in the membrane. In photoelectrosynthetic galvanic cells, chemical fuels may also be formed. This general strategy for dye sensitization has been employed in many guises over the years, but the absolute efficiencies remain very low. Albery concluded that an efficiency of

Figure 6. A regenerative photogalvanic cell where excited state electron transfer yields charge separated pair, D^+ and A^- , that are collected at dark electrodes.

~13 % could be theoretically achieved in a regenerative photogalvanic cell [22]. However, efficiencies realized to date are typically less than 2 %.

At negative potentials in the presence of electron acceptors, it is possible to produce cathodic photocurrents by a direct photoemission mechanism where electrons are photoejected from the metal directly into the solution [24]. Photoemission can be distinguished from dye sensitization by measuring the photocurrent yield as a function of excitation wavelength, a photocurrent action spectrum described further below. Barring competitive light absorption, the photoaction spectrum for dye sensitization is coincident with sensitizer absorptance spectrum, while photoemission currents increase continuously with the energy of the exciting photon. Photoemission is known to be inefficient in photoelectrochemical cells with quantum yields typically $< 10^{-4}$ [24].

Semiconductor sensitization

Anodic photocurrent generation is the most common and efficient mechanism by which photocurrents are generated at n-type semiconductors. A pictorial representation of a Gerischer diagram for the accepted mechanism is given in Figure 7. Corresponding diagrams for p-type sensitization have been proposed, but have received relatively little experimental attention [25]. For the case shown, the excited state reduction potential lies more than the reorganization energy above the conduction band edge, $E^\circ(S^{+/*}) - \lambda > E_{CB}$, and maximum overlap of the sensitizer excited state donor levels and the wide band is attained. This gives rise to the maximum electron transfer rate, i.e., activationless interfacial electron transfer. The excess

Figure 7. Gerischer's diagram for sensitization of a n-type semiconductor by an excited state sensitizer S^* .

energy of the injected electron is dissipated through lattice vibrations (phonons) as the electron thermalizes to the conduction band edge. Injection is therefore irreversible and repopulation of the excited state has never been observed.

The fate of the injected electron is expected to depend on the bias condition of the semiconductor. If injection occurs when the semiconductor is near the flat band condition (Figure 7a) then rapid recombination with the oxidized dye results because there is no electric field region to assist the spatial separation of the injected electron and oxidized hole. If the semiconductor is under depletion conditions, then the injected electron is swept toward the bulk by the surface electric field and recombination is inhibited (Figure 7b). Therefore, the current onset in photocurrent–voltage measurement can be taken as a crude estimation of the flat-band potential. The enhanced lifetime of the charge-separated state at molecular–semiconductor interfaces under depletion conditions allows the sensitizer to be regenerated by an external electron donor or by diffusional replacement with a new sensitizer and a net anodic photocurrent may flow. Spitler has proposed an Onsager model that predicts that a higher semiconductor doping level will result in more efficient spatial separation of the injected charge due to the larger average field [26]. Unfortunately, no experimental studies have been performed to test this model.

Photoelectrochemical techniques

Photocurrent–voltage behavior

Measurements of the photocurrent–voltage (i – V) and photovoltage properties describe the energy conversion properties of dye-sensitized photoelectrochemical cells and are probably the best fundamental method for their evaluation. This data can be acquired in a two- or three-electrode configuration. Figure 8 shows sche-

Figure 8. Hypothetical photo-current-voltage curve measured in a two-electrode arrangement. The short circuit photocurrent, i_{sc} , open circuit photovoltage, V_{oc} , and power point are indicated.

matically a hypothetical photocurrent-voltage curve measured in a two-electrode arrangement. The photocurrent measured under short-circuit conditions, i_{sc} , is often divided by the illuminated area and abbreviated j_{sc} . The open-circuit voltage, V_{oc} , is the potential of the illuminated electrode when no net current flows and represents the maximum Gibbs free energy that a regenerative solar cell will produce under conditions of constant irradiance [12]. The optimum conditions for solar energy conversion correspond to the maximum product of the cell voltage and photocurrent obtained along the i - V curve, and define the power point, pp. The maximum power is always assigned a positive value, regardless of the sign convention for photocurrent and photovoltage determination. The fill factor (FF) given by Eq. 11:

$$FF = (i_{pp} V_{pp}) / (i_{sc} V_{oc}) \quad (11)$$

in terms of the current and voltage measured at the power point, i_{pp} and V_{pp} , respectively. A fill factor of unity is ideal, but values <0.8 are most common owing to various resistive loss mechanisms and recombination. The maximum energy conversion efficiency, η_{max} , is defined by Eq. 12:

$$\eta_{max} = (i_{pp} V_{pp}) / (\text{absorbed optical input power}) \quad (12)$$

Maximum energy conversion efficiencies of $\eta_{max} = 0.1086$ have recently been measured and verified for dye-sensitized regenerative cells illuminated with air mass 1.5 simulated solar irradiation [27]. The efficiency of photoelectrosynthetic cells must also include contributions from the free energy stored in the chemical products of the reduction and oxidation reactions.

Models of i - V data for sensitized electrodes invariably begin with Gartner's treatment developed for solid-state junctions [28] that was later extended to photoelectrochemical cells by Butler [29]. In Gartner's model, light absorption by the semiconductor itself yields a photocurrent that contains a drift component asso-

ciated with carriers generated within the depletion region, and a diffusional component for minority carriers created in the neutral bulk that reach the depletion region before recombining [28]. The relative amplitudes of the two photocurrent components are controlled in part by the absorption coefficient of the exciting light, α . The optical generation of minority carrier is given by Eq. 13:

$$G(x) = I_0 \alpha e^{-\alpha x} \quad (13)$$

where $G(x)$ is the generation rate and I_0 is the intensity of the light. The generation rate in dye-sensitized electrodes can be defined analogously with the sensitizer's effective absorption coefficient. Gartner derived Eq. 14 for the photocurrent–voltage behavior:

$$i_{\text{ph}} = I_0 \left(1 - \frac{e^{-\alpha W}}{1 + \alpha L_p} \right) \quad (14)$$

where L_p is the diffusion length. Note that Gartner's expression predicts a substantial photocurrent at the flat-band potential ($W = 0$) [28]. This is due to the fact that in this simple model, important experimental variables, such as space-charge and surface state-mediated recombination and the dark current, are ignored. More complex models that take these and other variables into account, have been described in the literature [30–32].

The relevance of Gartner's model, in spite of its obvious shortcomings, underscores the inadequacy of simple i – V curves for understanding loss mechanisms in sensitized solar cells. The common, but crude, approach of using photocurrent onsets as a measure of the flat-band potential, alluded to above, is actually fraught with difficulties unless fill factors are high and the system behaves nearly ideally. In most cases, the determination of photocurrent onset requires high excitation irradiance (which may in itself shift the band edges) and abstraction of weak photocurrents from larger dark currents. When the sensitized material does not behave ideally, the actual flat-band potential is usually considerably more negative than that estimated from i – V curves.

Photoaction spectra

A plot of the photocurrent quantum yield versus excitation wavelength is termed the 'photoaction' or 'photocurrent action' spectrum. These spectra are obtained at short-circuit in a two-electrode arrangement or with an external bias in a three-electrode configuration. The photocurrent quantum yield is defined as the number of electrons measured in the external circuit divided by the number of absorbed photons. It is experimentally difficult to calculate the number of absorbed photons and corrections for scattered or transmitted light often appear to be 'fudge factors' that increase the uncertainty of the absolute photocurrent yield. Therefore, the incident photocurrent yield is often reported which represents a lower limit of the true photocurrent quantum yield.

Although it is often stated that the photoaction and absorption spectra should be coincident, this is not technically correct. Photoaction spectra of sensitized electrodes in photoelectrochemical cells are sensitive to the fraction of light absorbed by the sensitizer. The absorptance is the IUPAC recognized term for the fraction of incident radiant power absorbed by a chromophore [33]. The term 'light harvesting efficiency' (LHE) is occasionally employed in the dye-sensitization literature and is mathematically equivalent to the absorptance. The absorptance and absorption are approximately equal when the fraction of light absorbed is very small. For thick films of sensitizers or under conditions where species in the electrolyte absorb light, trivial inner filter effects and competitive light absorption can also affect the shape of the photocurrent action spectrum.

Time-resolved techniques

Steady-state photocurrent–voltage behavior quantifies the bottom line efficiency of operational solar cells. Unfortunately, it provides little molecular information, particularly when the photocurrent yields are low. A variety of transient, time and frequency domain electrochemical techniques have been employed to provide further insights into the molecular origin of loss mechanisms. Space restrictions do not allow these electrochemical techniques to be discussed here [34–37].

2.1.2 Examples of Sensitization Studies at Planar Electrodes

Metal electrodes

Photogalvanic cells

Some of the first examples of dye sensitization were the celebrated photogalvanic cells [22, 23, 38–42]. Recall that in these cells, charge separation occurs by excited state intermolecular electron transfer and the redox equivalents are collected at dark electrodes. Photogalvanic cells can be regenerative or photoelectrosynthetic. In many experimental studies, highly doped tin oxide electrodes were employed to allow uniform illumination of thin solutions. While the tin oxide electrodes could display semiconducting behavior, the materials are highly doped, degenerate semiconductor and space-charge contributions to electron collection are thought to be minimal. Indeed, in many cases the collection efficiencies of highly doped SnO_2 and metallic electrodes are found to be the same.

The Iron–thionine system

The first attempts to understand the mechanism of operation of photogalvanic cells was performed on the iron–thionine system [22, 23]. Here we summarize the main observations. Thionine (Th) is a cationic purple dye extremely soluble as the chloride salt. Two other forms of the compound, Leukothionine (L) and Semithionine (S[•]), are also important in the sensitization process and their structures are shown in Figure 9. According to Albery, the light driven redox reactions that lead to a photocurrent are as follows:

Figure 9. The compounds thionine (Th), semithionine (S), and leukothionine (L) proposed to exist in iron-thionine photogalvanic cells.

In competition with photocurrent production, the Fe^{III} can oxidize S^* or L. Experimental data strongly suggests that recombination with S^* is the main factor that lowers overall efficiency [20]. Attempts to increase the efficiency by replacing thionine with $\text{Ru}(\text{bpy})_3^{2+}$ were not successful from a practical point of view [38]. Other issues regarding the optimum diffusion length, solute concentration and selectivity of the electrodes have been considered. Theoretical solar conversion efficiencies of 0.13 are believed to be achievable by this general approach. The highest efficiency measured to date is only $\sim 3 \times 10^{-4}$ [23].

Photogalvanic cells with chlorophylls, porphyrins, phthalocyanines and other chromophores have been studied [38–42]. An example is the chlorophyll *a*–hydroquinone (Chla– H_2Q) galvanic cell [40]:

Light excitation of a Chla membrane deposited on Pt resulted in a weak photocurrent with the Pt/Chla behaving as a cathode. The photocurrent action spectrum resembled the Chla absorption spectrum which ruled out a direct photoemission process. The direction of the photocurrent was rationalized by invoking a p-type conductivity in the Chla films. Bolton and co-workers explored related monolayer assemblies with spatially organized quinones to increase efficiencies [41]. In a more promising system, Chla monolayers deposited on Al contacts with uboquinone ac-

Figure 10. A self-assembled monolayer comprised of terminal porphyrins, intermediate ferrocenes, and surface thiols attached on gold surface. The solid line is the photoaction spectrum, the dashed line is the absorption spectrum. Panels a) and b) show the proposed mechanisms, and c) provides the structure of the thiol ferrocene-porphyrin complex.

ceptors yielded $V_{OC} = 270$ mV and $j = 140$ nA cm⁻² under 100 W m⁻² excitation irradiance [41]. Gust and co-workers described more elaborate donor-sensitizer-acceptor assemblies that yield a measurable photogalvanic response [42].

Self-assembled monolayers

An innovative approach for the sensitization of metal electrodes was recently reported [43]. Monolayers comprised of terminal porphyrins, intermediate ferrocenes and surface thiol were self-assembled on to gold surface. The strategy in the design of the self-assembled monolayers (SAMS), and the related energetics are shown schematically in Figure 10. Light absorption by the porphyrin initiates a series of electron transfer reactions that ultimately yield a reduced electron acceptor in solution and removal of an electron from the metal. A cathodic photocurrent was observed with a monochromatic quantum yield of 0.11 at the absorption maximum with methylviologen acceptors in solution. The sequence of photodriven electron transfer events remains unknown. It may in fact be best classified as a photogalvanic cell. Photocurrent versus potential measurements demonstrate that the efficiency increases significantly when the ferrocene iron is in the +2 oxidation state [43]. The mechanism, therefore, probably includes ferrocene-mediated electron transfer to the excited or oxidized porphyrin.

The photocurrent yield of these novel SAMS is higher than any previously measured at sensitized metal electrolyte interfaces [43]. It was suggested that the fixed distance imparted by the alkanethiol layer decreases the efficiency of energy transfer

Figure 11. The structures of currently utilized sensitizers for the sensitization.

quenching or back electron transfer by the metallic electrode. Multistep electron transfer at a gold electrode modified with a ferrocene–porphyrin–C₆₀ triad SAMS has also been reported to yield sustained photocurrents [44, 45]. Photocurrents observed from the SAMS appear to be more stable than those observed with excitation of Langmuir–Blodgett monolayers [46–49]. These observations are encouraging and suggest that with further optimization it will be possible to efficiently harness solar energy with sensitized metal interfaces.

Metal oxide semiconductors

Early studies

Sensitization of wide band-gap, n-type metal oxide semiconductors to visible light was among the first sensitization studies in photoelectrosynthetic cells. The most common semiconductors were SnO₂, TiO₂ and SrTiO₃ and the sensitizers (Figure 11) were Rhodamine B [50–57], Ru(bpy)₃²⁺ [58–65], Ru(bpy)₂(dcb)²⁺ [66–68] and other organic chromophores [69–73]. This work was inspired, at least in part, by the famous water splitting experiments of Fujishima and Honda and the hope that sensitized materials could accomplish the same feat with visible light [74]. Although the photocurrent and water splitting yields were low, these studies provide important experimental data for current and future research. Below we summarize these findings from a historical point of view using Ru(bpy)₃²⁺ as the model sensitizer.

Gleria and Memming first sensitized tin oxide to visible light with Ru(bpy)₃²⁺ in pH 1 aqueous electrolyte [58]. A sustained photocurrent was observed under conditions of positive applied potentials. The photoaction spectra were reported to be slightly red-shifted, but otherwise closely resemble the absorption spectra of the sensitizer in fluid solution. The mechanism proposed was excited state electron transfer to the conduction band. The Ru(bpy)₃³⁺ product was thought to oxidize water with an apparent rate constant of $9 \times 10^2 \text{ s}^{-1}$ and the injected electron gave rise to the measured photocurrent [60]. Interestingly, the rate constant measured for water oxidation was over 1000 times greater than the rate measured previously in the dark [75]. This discrepancy has never been fully resolved [76].

An interesting potential dependence to the sensitized photocurrent was reported by Memming for heavily doped tin oxide semiconductors. At positive applied po-

Figure 12. Enhanced electron tunneling from heavily doped SnO_2 to the oxidized sensitizer.

tentials, beyond the plateau in the photocurrent–voltage curve, the photocurrent decreased under conditions when a dark current also became significant [60]. Under the same conditions, weakly doped tin oxide showed no photocurrent decrease. Memming attributed this effect to enhanced electron tunneling to the oxidized sensitizer through the relatively thin space-charge layer of the heavily doped tin oxide electrode, as shown schematically in Figure 12. Similar behavior was observed by other researchers [52]. A related explanation for this behavior is that the dark currents that become significant at these potentials deplete the surface region of oxidizable species leaving a lower concentration to scavenge the oxidized sensitizer thereby allowing a larger fraction to recombine with electrons in the semiconductor.

Following Osa and Fujihira's studies with Rhodamine B [56], Goodenough and co-workers reported the covalent attachment of $\text{Ru}(\text{bpy})_2(\text{dcb})^{2+}$ to SnO_2 and TiO_2 surfaces, through the dehydrative coupling of surface hydroxyl groups with the carboxylic acid groups [66]. The product of this reaction was assumed to be surface ester linkages and water. It was proposed that surface ester linkage in the 4- and 4'-positions of bipyridine would enhance electronic coupling between the π^* orbitals of the bipyridine ligand and the Ti 3d orbital manifold of the semiconductor. The measured photocurrent yield was very low and the photoaction spectrum did not resemble the known solution absorption spectrum suggestive of direct charge transfer from the sensitizer ground state to the conduction band continuum [66]. A red shift in the photoaction spectra of the complex that increases with applied pressure was subsequently reported [68]. However, these authors concluded that sensitization involves excited state interfacial electron transfer rather than direct transfer to the CB [68].

Probing Gerischer's distributions

Clark and Sutin studied the photosensitization of rutile TiO_2 single crystals in dilute aqueous solution by $\text{Ru}(\text{bpy})_3^{2+}$ and two closely related Ru^{II} sensitizers that have different excited state reduction potentials, $\text{Ru}[4,7-(\text{CH}_3)_2\text{-phen}]_3^{2+}$, where 4,7-(CH_3)₂-phen is 4,4'-dimethyl-1,10-phenanthroline, and $\text{Ru}(5\text{-Cl-phen})_3^{2+}$ [63].

Figure 13. Conduction band edge, E_{CB} shifts as a function of solution pH relative to the indicated excited state distribution of RuL_3^* compounds, W_{don}^* , vs SCE reference.

Clark and Sutin took advantage of the known 59 mV per pH unit shift of the conduction band edge to probe Gerischer's distributions directly as shown schematically in Figure 13 [77]. An anodic photocurrent was observed in acidic solution under conditions of positive applied potential, consistent with excited state electron transfer to the TiO_2 . Watanabe and co-workers had previously observed decreased photocurrents at high pH relative to low pH for electrodes sensitized with Rhodamine B [52]. Photoelectrochemical measurements as a function of solution pH revealed that $Ru(5\text{-Cl-phen})_3^{2+}$ required the lowest pH to generate a measurable photocurrent while $Ru[4,7-(CH_3)_2\text{-phen}]_3^{2+}$ gave a photocurrent at the highest pH. The trend observed indicates that the pH onset originates from the variations of the sensitizer excited state reduction potentials. This finding suggests that the pH onset in photocurrent titration experiments of this kind could be used to determine the excited state reduction potential of nonemissive or unknown sensitizers. Furthermore, analysis of the pH–photocurrent data allowed the reorganization energy for excited state electron injection to be measured, $\lambda = 0.7$ eV. Spitler and co-workers calculated λ analogously from the pH-dependent sensitization of $SrTiO_3$ by two adsorbed dyes, 2,2'-diethylthiacarbocyanine and 2,2'-diethyloxadiazocarbocyanine. Values of between 0.3 and 0.4 eV were estimated and the authors concluded that the Gerischer formulation of electron transfer may be applied with confidence to reactions of species adsorbed at the semiconductor electrolyte interface [69].

Clark and Sutin [63] reported that the quantum yield for electron injection from $Ru[4,7-(CH_3)_2\text{-phen}]_3^{2+*}$ to rutile TiO_2 was unity at pH 1 but dropped to zero at higher pH. At that time, a quantum yield of unity had little precedence. Spitler and Calvin had measured adsorption isotherms and sensitized photocurrent quantum yields for Rose Bengal/ TiO_2 ⁷¹ and Rhodamine B/ ZnO [53] and reported surface coverage-independent values of less than 0.03. The results suggested that only a

small fraction of semiconductor adsorption sites allowed excited state electron injection. On the other hand, self-quenching of excited Rhodamine B* at high surface coverages on TiO_2 has been reported by several groups using luminescence and/or photoelectrochemical techniques [50, 51, 54].

'Supersensitization' mechanisms

Sensitized n-type semiconductors have been known to yield higher photocurrent efficiencies when electron donors such as iodide, hydroquinone or triethanolamine were added to an aqueous electrolyte. These donors are often referred to as 'supersensitizers' because their presence so dramatically increases the photocurrents. The mechanism of 'supersensitization' was often attributed to efficient reduction of the oxidized sensitizer allowing a greater fraction of the injected electrons to be converted to a photocurrent. This was a perfectly reasonable suggestion as most of these cells were designed to oxidize water at the photoanode, which is an inherently sluggish process.

An alternative reductive quenching mechanism for the 'supersensitizer' sensitization of metal oxide semiconductors has been explored in considerable detail by Kirsch-De Mesmaeker and co-workers [78–82]. These researchers found that unlike $\text{Ru}(\text{bpy})_3^{2+}$, sensitizers such as $\text{Ru}(\text{tap})_3^{2+}$ did not inject electrons into the semiconductor from the excited state, yet an anodic photocurrent was observed when an electron donor such as hydroquinone (H_2Q) was present in the electrolyte. The sensitization mechanism they proposed is distinctly different from 'trapping' the oxidized sensitizer described above, and is more similar to that proposed for photogalvanic cells. In the presence of H_2Q , excited state intermolecular electron transfer yields $\text{Ru}(\text{tap})_3^+$. The photogenerated $\text{Ru}(\text{tap})_3^+$ is a strong reductant (-0.76 V vs. SCE) that injects an electron into the SnO_2 conduction band which is measured as a photocurrent (Figure 14).

Figure 14. An alternative reductive quenching sensitization mechanism explored by Kirsch De Mesmaeker using $\text{Ru}(\text{tap})_3^{2+}$ which is not thermodynamically capable of injecting an electron into SnO_2 conduction band from the excited state, but can from reduced state.

Table 1. Photoluminescence quenching and steady-state photoelectrochemical data for $\text{Ru}(\text{tap})_3^{2+}$ – H_2Q systems.

Complex	τ_0/ns	$K_{\text{SV}}^{\text{PEC}}/\text{M}^{-1}$		$K_{\text{q}}^{\text{PEC}}/10^9\text{M}^{-1}\text{s}^{-1}$		$K_{\text{SV}}/\text{M}^{-1}$	$k_{\text{q}}/10^9\text{M}^{-1}\text{s}^{-1}$
		$E = 0.1\text{ V}$	$E = 0.2\text{ V}$	$E = 0.1\text{ V}$	$E = 0.2\text{ V}$		
$\text{Ru}(\text{tap})_3^{2+}$	200	1350	1510	6.7	7.5	900	4.9
$\text{Ru}(\text{Me}_2\text{tap})_3^{2+}$	90	465	521	5.1	5.7	470	5.2

Strong evidence for this sensitization mechanism came from a comparison of the excited state quenching rate constant and the photocurrent enhancement by the same donor. Photoelectrochemical Stern–Volmer constants were measured with the aid of Eq. 19:

$$\frac{I_{\infty} - I_0}{I - I_0} = 1 + \frac{1}{k_{\text{q}}^{\text{PEC}}\tau_0[\text{Q}]} = 1 + \frac{1}{K_{\text{SV}}^{\text{PEC}}[\text{Q}]} \quad (19)$$

where I , I_0 and I_{∞} are the steady-state potentials measured in the presence, absence and at high donor concentration, respectively, $k_{\text{q}}^{\text{PEC}}$ and $K_{\text{SV}}^{\text{PEC}}$ are the photoelectrochemical quenching and Stern–Volmer constants, respectively, τ is the excited state lifetime and $[\text{Q}]$ is the molar quencher concentration. The excited state was monitored by photoluminescence and the reductive quenching by D was monitored by the more familiar Stern–Volmer model, Eq. 20:

$$\frac{PLI_0}{PLI} = 1 + \frac{1}{k_{\text{q}}\tau_0[\text{Q}]} = 1 + \frac{1}{K_{\text{SV}}[\text{Q}]} \quad (20)$$

where PLI_0 and PLI are the photoluminescence intensity measured without and with quencher, Q, respectively.

Table 1 shows that the quenching and Stern–Volmer constants measured by the two techniques are in good agreement. This supports the idea that H_2Q quenches the excited state directly rather than reducing the oxidized sensitizer after electron transfer. The $\text{Ru}(\text{tap})_3^{+}$ produced from excited state quenching is a stronger reducing agent than is the excited state, by $\sim 640\text{ mV}$, as shown schematically. This additional driving force for interfacial electron transfer can allow sensitizers that are weak excited state reductants to sensitize semiconductors. Spectroscopic evidence for this mechanism has also recently been reported [83]. Taken together, these observations call into question the proposed ‘supersensitization’ mechanism(s) in early dye sensitization studies of wide band-gap metal oxide semiconductors.

Cathodic photocurrents

Cathodic photocurrents have been observed near the flat-band potential or at more negative potentials in the presence of dioxygen or other electron acceptors with sensitized and unsensitized wide band-gap semiconductor electrodes [84–88]. Al-

Thiapentacarbocyanine

Figure 15. Structure of thiapentacarbocyanine.

though alternative mechanisms have been proposed, it appears that all the data can adequately be rationalized by the mechanism previously described for photo-galvanic cells. The excited sensitizer transfers an electron to the acceptor and is then reduced by an electron in the semiconductor.

Small bandgap semiconductors

Layered semiconductors

The van der Waals surfaces of layered n-type semiconductor single crystals, such as SnS_2 , WS_2 and WSe_2 , have excellent characteristics for dye sensitization studies including atomically flat, defect-free surfaces that are renewable by cleavage under ambient conditions. Parkinson and others have explored the sensitization of this class of semiconductors with a wide variety of organic chromophores [89–93]. For example, efficient infrared dye sensitization of layered semiconductors n- WS_2 and n- WSe_2 was achieved with the thiapentacarbocyanine dye shown in Figure 15. The sensitized electrode behaves as a photoanode, as expected, and absorbed photon-to-current yields of 0.8 were estimated. The sensitized photocurrent densities were in excess of $40 \mu\text{A cm}^{-2}$ with aqueous hydroquinone electrolytes. Photocurrents reported at 1200 nm represent the longest wavelength semiconductor sensitization available in the photoelectrochemical literature [92].

An intriguing feature of the WSe_2 electrodes sensitized with the thiapentacarbocyanine was that the photocurrent action spectra were a function of the bias potential applied to the electrode. For example, the maximum conversion efficiency at $-0.4 \text{ V vs. Ag/AgCl}$ was 1100 nm but shifted to 1080 nm at $+0.05 \text{ V}$. The origin of these spectral shifts was attributed to sensitizer aggregates formed on the surface that have different conversion efficiencies [92].

Two research groups have measured the rate of excited state electron injection into SnS_2 with time-resolved fluorescence techniques. Willig and co-workers studied excited Cresyl Violet monomers at about 1 % of full monolayer coverage on SnS_2 [90]. Here the Cresyl Violet excited singlet-state reduction potential lies more than the reorganization energy above the estimated value of the conduction band edge, i.e., $E(S^{+/*}) - \lambda \gg E_{\text{CB}}$, so electron injection was expected to be activationless and the measured electron injection rate constant would correspond to the maximum in

Gerischer's distribution curve [89]. Injection was found to occur in less than 10 ps, providing the first clear indication of the relevant time-scale at the maximum of Gerischer's distribution. Two years later, Lanzafame and co-workers [89] reported femtosecond fluorescence studies of oxazine 1 adsorbed to the same semiconductor. Injection from the oxazine 1 singlet state was also activationless and an injection rate of approximately $3 \times 10^{13} \text{ s}^{-1}$, corresponding to an electron transfer time of $40 \pm 20 \text{ fs}$ was reported. The corresponding localization of the injected electron to the semiconductor conduction band edge was observed to occur in 1–10 ps. Theoretical justification for this rapid injection rate was also given [89].

Organic semiconductors

An important class of sensitized solar cells consists of an organic thin film, such as phthalocyanines, perylenes, chlorophylls or porphyrins, sandwiched between two metal electrodes. The interfacial regions are often modeled as Schottky junctions where the organic layer is considered to be small band-gap semiconductor with either n- or p-type photoconductivity [94–96]. In a related approach, a p-type organic film is deposited on top of an n-type organic film to form a p–n heterojunction. The sensitization mechanisms proposed for these materials often incorporate addition mechanistic steps such as excitonic energy transfer through the organic layer to the electrode where interfacial electron transfer takes place. It is not clear how important these proposed mechanistic steps are for most materials. The strategy of using thick sensitizer films to increase the fraction of light absorbed generally results in decreased photocurrent efficiency. For semiconducting sensitizer films, the reported excitonic diffusion lengths are short relative to the penetration depth of the light. Furthermore, excitons are readily quenched by impurities or incorporated solvent. In most cases it appears that the small photocurrents observed could simply be rationalized by interfacial electron transfer from localized excited states proximate to an electrode followed by charge migration in the organic layer to the opposite electrode.

In early studies, the two metals employed had different work functions that were incorporated to promote vectorial charge separation. Tang and Albrecht deposited chlorophyll-a (Chla) (Figure 16) on Cr or Al electrodes and then used a liquid metal, Hg or In, as the second electrode [97–99]. These cells are similar in some respects to the photogalvanic cells studied by Bolton and co-workers [41] and Fong and co-workers [40], except that no redox active electrolyte was employed. In the solid-state sandwich cells, the steady-state photocurrent and photovoltage transients resembled the solution absorption spectrum of Chla. The power conversion efficiencies were of the order of 10^{-4} – 10^{-5} with monochromatic light illumination. By applying a bias, the yield was increased to 0.03. In cells better optimized for solar energy conversion, merocyanine dyes have exhibited efficiencies greater than 1 % and monochromatic efficiencies near 100 % [100]. An impressive power efficiency of 1.8 % was reported for an organic heterojunction at low irradiance [101]. Some novel organic multilayer sensitized electrodes have also recently been fabricated [102, 103].

Bard and co-workers explored the effects of doping and illumination on the

Figure 16. Structure of chlorophyll a and phthalocyanine.

Figure 17. Effect of front side and back side illumination of semiconductor electrodes coated with phthalocyanine thin films. The direction of the photocurrent could be controlled by illumination direction and the redox couple in the solution.

photocurrent direction and magnitude for phthalocyanine (Pc) (Figure 16) films deposited on wide band-gap semiconductors and metals in wet photoelectrochemical cells [104–107]. For example, when Pc thin films (100–250 Å) deposited on tin oxide electrodes were illuminated in a hydroquinone (H_2Q)–benzoquinone (BQ) aqueous electrolyte (Figure 17), the sign of the photocurrent was dependent on the excitation wavelength and the applied potential. With back-side illumination, the Pc^* excited states were formed preferentially near the SnO_2 interface and electron injection into the solid was favored, giving rise to an anodic photocurrent. This process was also observed when the Fermi level is low, i.e., at positive applied potential. With front-side illumination the excited states were preferentially formed near the Pc–electrolyte interface where excited-state electron transfer to BQ was

avored. The hole was transferred to the SnO_2 interface, yielding a net reductive photocurrent. The magnitude and spectral distribution of the current were also sensitive to the metal ion in the Pc. Free base, Zn^{II} and Mg^{II} phthalocyanine gave large reductive photocurrents that are sensitive to E° of the electroactive couple present in the electrolyte. Interpretation of the photoaction spectra was complicated by competitive light absorption and the change in current direction for wavelengths of light with different penetration depths. The observed photoaction spectra could be qualitatively understood and, if only H_2Q was present, an anodic photocurrent was measured that agreed well with the solution absorption spectra.

More recently, liquid crystalline porphyrins sandwiched between two indium tin oxide electrodes were characterized by Bard and co-workers [108]. A memory effect was observed where upon irradiation of the organic film with the simultaneous application of an electric field, electron-hole pairs were generated and separated within the photoconductive porphyrin layer. These electron-hole pairs remained after the illumination of the cell was interrupted and could be released by irradiation of the cell, resulting in a transient short-circuit photocurrent. The high degree of order in the liquid crystalline layers appears to accentuate these processes relative to more disordered films prepared by spin coating or sublimation techniques. The authors suggested that this finding could be exploited for read-write data storage applications [108].

Usually the direction of current flow in sensitized cells is easily rationalized by considering the relative energetics and constructing a Gerischer-type diagram. Bard and co-workers' work provides an excellent example of this [104–107]. However, in some systems the direction of current flow is unexpected. A case in point is an unusual photoeffect reported by Gregg and co-workers [109–112]. Liquid crystalline porphyrins deposited between two tin oxides were found to yield a significant photovoltage and a small photocurrent. This is unexpected since the cell is symmetric with no built-in asymmetry or internal electric fields that might cause preferential vectorial charge transfer toward one electrode. Charge separation appears to be entirely driven by a kinetic effect. Electron injection from Pc^* into the tin oxide is more facile than is hole injection. Therefore, the illuminated surface yields an anodic photocurrent generated solely by the relative rate constants for interfacial electron transfer. Further studies of this behavior have been reported [109–111].

2.2 Dye Sensitization of Colloidal Semiconductor Electrodes

A practical disadvantage of the sensitized planar electrodes described in the previous section was their low solar energy conversion efficiencies. An experimental drawback was that characterization was limited to photoelectrochemical or luminescence techniques. Both of these issues arose from the poor light harvesting by monolayers on flat surfaces or inefficient interfacial electron transfer yields from thick films or concentrated solutions. In 1990, Grätzel and co-workers reported experimental studies of dye sensitized colloidal TiO_2 films that eliminated both of these problematic issues [112]. The effective surface area for sensitizer binding

was increased by about 1000-fold over that of a planar electrode and the interfacial injection yields were close to unity. Solar conversion efficiencies of $\sim 5\%$ were realized soon thereafter [113] and this efficiency has been optimized to 10.69% today [27]. The stability and current densities suggest a practical approach to solar energy conversion that has renewed interest in this area. Furthermore, time-resolved spectroscopic techniques can now be employed in conjunction with traditional photoelectrochemical techniques to probe dye sensitization mechanisms in molecular detail that was not previously possible [112].

The mechanism for anodic photocurrent generation at a sensitized n-type semiconductor, described in Section 1.1.1, is generally believed to be the operative mechanism for the sensitized nanocrystalline TiO_2 regenerative cells. A simplified schematic illustration is shown. An excited sensitizer, S^* , injects an electron into the semiconductor, with rate constant k_{inj} . The oxidized dye molecule accepts an electron from a donor present in the electrolyte, k_{red} . Iodide is the donor shown in Figure 18. The iodide oxidation products are reduced at the dark cathode. The net process allows an electrical current to be generated with light of lower energy than the semiconductor band-gap with no net chemistry. Charge recombination, k_{cr} , can occur to the oxidized sensitizer, S^+ , or donor.

Since the accepted mechanism for dye sensitization has been described in Section 1.1, it will not be elaborated on further here. Instead, the materials and spectroscopic, and photoelectrochemical properties of sensitized colloidal semiconductor films will be discussed in the next section. Nanocrystalline (anatase) TiO_2 films sensitized to visible light with Ru(II) coordination compounds are the best studied and will be focused upon here. Colloidal semiconductor films suitable for dye sensitization based on SnO_2 [114], Fe_2O_3 [115], Nb_2O_3 [116] and ZnO [117] have recently been developed but have received far less attention. Section 1.2.2 gives a progress report of photoinduced electron transfer studies that are ongoing in this active research area.

2.2.1 Materials, Spectroscopic and Electrochemical Properties of Nanocrystalline TiO_2

Materials

The preparation of nanocrystalline semiconductor films generally follows sol–gel procedures or takes advantage of commercially available particles, such as Degussa P-25 TiO_2 [118]. A typical sol–gel preparation is briefly described here. Titanium isopropoxide [$\text{Ti}(i\text{-PrO})_4$] is added to vigorously stirred acidic water, heated to 80°C , and subsequently heated under pressure for 12 h between 200 and 250°C . This procedure yields anatase particles that are between 8 and 20 nm in diameter depending on the temperature. The volume of the solution is then adjusted and a surfactant, such as poly(ethylene glycol), $\text{MW} = 20\,500$, is added to form a viscous white paste. The paste is deposited on conductive tin oxide glass dried in air for 15 min and heated at 450°C for 1 h.

The resulting material is a mesoporous film comprised of interconnected anatase particles. The scanning electron micrograph shows ~ 10 nm size particles interconnected in a sponge-like 8–10 μm thick film [119]. The materials are typically 50–70 % porous and about two-thirds of the tin oxide substrate is covered with particles. The colloidal films are highly resistive with dark conductivity of $\sim 10^{-9} \Omega \text{ cm}^{-1}$ at 330 K. An activation energy of 1.6 eV has been reported, which suggests that the Fermi level is near midgap [120]. X-ray analysis reveals the anatase structure shown in Figures 19 and 20.

Figure 19. SEM image of a colloidal TiO_2 thin film.

Figure 20. Anatase structure of TiO_2 where filled balls are titanium and open circles are oxygen.

The semiconductor films are transparent in the visible region. Around 380 nm a sharp absorption onset is observed below which the films are strongly absorbing. The absorption has been assigned to the fundamental $\text{VB} \rightarrow \text{CB}$ transitions consistent with the known anatase band-gap of 3.2 eV. However, it is not clear how intra-band-gap transitions from localized states alter the absorption edge. Owing to the large effective mass of electrons in TiO_2 , the Bohr radius of TiO_2 is smaller than 1 nm, which indicates that size quantization effects are not expected to be observable in nanometer-sized TiO_2 particles [121].

Sensitizers

Surface binding

The most common mode for surface binding inorganic and organic sensitizers is through the reaction of carboxylic acid groups with the metal oxide surface in neat acetonitrile or alcohol. Phosphonates [122], acetylacetonates [123], ether linkages [124] and cyano [125] groups have also been employed for binding to metal oxides but thus far have resulted in less efficient solar cells.

The reaction of carboxylic acids with surface hydroxyl groups to form ester linkages (Figure 21) was initially suggested by Goodenough et al. [67] for $\text{Ru}(\text{bpy})_2(\text{dcb})^{2+}$ and by Osa and Fujihira [56] for Rhodamine B. The nature of the surface linkage has been studied by several groups using vibrational spectroscopy [126–130]. Hester and co-workers used Raman spectroscopy to identify the binding mode(s) of $\text{Ru}(\text{dcb})_3^{2+}$ on colloidal TiO_2 particles suspended in acidic solution [126]. They concluded that the sensitizers hydrogen bond to the semiconductor surface. Many other groups have examined the chemistry of *cis*- $\text{Ru}(\text{dcb})_2(\text{NCS})_2$ and $\text{Ru}(\text{bpy})_2(\text{dcb})^{2+}$ anchored to colloidal TiO_2 films by infrared spectroscopy [127–129]. In all cases a low-energy asymmetric CO_2^- stretch is observed that is most consistent with carboxylate binding, rather than ester. It is likely that the nature of the surface linkage is dependent on the surface conditions. Even for X-ray

Figure 21. Surface binding through the dehydrative coupling of carboxylic acid groups with surface hydroxyl groups to yield ester linkages and water.

crystallographically characterized metal carboxylates, the coordination modes are known to be sensitive to sample preparation [130].

The concentration-dependent binding of Ru(dcb)-based sensitizers is well described by the Langmuir adsorption isotherm model from which adduct formation constants of $\sim 10^5 \text{ M}^{-1}$ have typically been abstracted [123, 132]. While it is often stated that monolayer coverage of the sensitizers is achieved, this is difficult to prove. The colloidal nature of the films makes absolute surface area determinations almost impossible. There is no evidence for multilayer formation, so the surface coverage is at most monolayer and probably sub-monolayer in most cases. The surface coverage for sensitizers in a 1 cm^2 geometric area is typically 10^{-8} mol , where $\sim 10^{-10} \text{ mol cm}^{-2}$ would be expected for a close-packed monolayer of 14 \AA diameter sensitizers on a flat surface.

Electrochemistry

Ru(bpy)₂(dcb)²⁺ anchored to nanocrystalline TiO₂ films displays quasi-reversible Ru^{III/II} redox chemistry [123, 132, 134]. The redox chemistry is termed quasi-reversible because the oxidation and reduction current are the same within experimental error and the peak-to-peak splitting is large [7]. This redox chemistry does not involve the semiconductor valence or conduction bands. Rather the proposed mechanism is that a small fraction of the sensitizers, $< 10^{-10} \text{ mol cm}^{-2}$, bound to the SnO₂ substrate are initially oxidized electrochemically. These oxidized sensitizers mediate the oxidation of TiO₂-bound sensitizers by self-exchange electron transfer across the nanocrystalline surface(s). Cyclic voltammetry is therefore a useful technique for characterizing the ground-state potentials of semiconductor-bound sensitizers. The technique has been utilized for sensitizers with only one carboxylic acid group and those bound through alternative linkages [123]. Unfortunately, it has not been successfully applied to the commonly used *cis*-Ru(dcb)₂(NCS)₂ sensitizer that displays irreversible electrochemistry in fluid solution at scan rates less than 200 mV s^{-1} [133].

Trammell and Meyer used cyclic voltammetry and chronoamperometry with absorption measurements to estimate the electron hopping rate across sensitized nanocrystalline semiconductor surfaces [134]. At high surface coverages of Ru(bpy)₂(dcb)²⁺ or Os(bpy)₂(dcb)²⁺, the apparent charge-transfer diffusion coefficients was measured to be $1.4 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$ in acetonitrile electrolyte. Oxida-

tion of the surface-bound sensitizers could also be accomplished with a mediator present in the electrolyte. Bonhôte and co-workers applied a percolation model to the kinetics of cross-surface electron transfer for an organic triarylamine bound to nanocrystalline TiO_2 surfaces [135].

Zaban and co-workers reported the use of chemical redox titrations to measure the potential of sensitizers bound to TiO_2 [136]. An unexpected result from these studies is that redox couples that are not pH sensitive in fluid solution become pH dependent when bound to the semiconductor surface. The magnitude of the pH-induced shift varied from 21 to 53 mV per pH unit depending on the physical location of the sensitizer. Sensitizers inside the semiconductor double layer track the $\sim 59 \text{ mV pH}^{-1}$ shift of the semiconductor. When sensitizers were outside the double layer, their potential was almost independent of the semiconductor. This finding has important implications for the determination of interfacial energetics for dye sensitization and interfacial electron transfer studies [136].

Photophysics

In general, the absorption spectra of sensitizers bound to colloidal semiconductor films closely resemble those measured in fluid solution. In some cases small spectral shifts have been observed and attributed to Stark effects, acid–base chemistry or stabilization of the sensitizer excited states by the semiconductor surface. However, the effects are small, typically a few nanometers in the visible region.

The accepted model for photocurrent generation in the dye-sensitized nanocrystalline solar cells involves excited state interfacial electron transfer. It is therefore desirable to have a mechanistic understanding of excited-state behavior of the sensitizers. Since the most successful sensitizers for this application are Ru^{II} polypyridyl compounds, we include a brief review of their excited-state properties. More thorough reviews are available in the literature [137].

The parent compound $\text{Ru}(\text{bpy})_3^{2+}$ has been extremely well studied and a Jablonski-type diagram is shown in Figure 22 [137]. Light absorption forms a metal-to-ligand charge transfer (MLCT) excited state wherein an electron is formally promoted from the metal d-orbitals to a bipyridine ligand, $\text{Ru}^{\text{III}}(\text{bpy}^-)(\text{bpy})_2^{2+*}$. Rapid and quantitative intersystem crossing to a manifold of thermally equilibrated MLCT excited states is observed in fluid solution. The thexi state consists of three energetically proximate states that have significant Boltzmann population and behave as a single state near room temperature. This thexi excited state has a lifetime near 1 μs in fluid solution and is highly photoluminescent. Higher in energy is a fourth MLCT state and ligand field (LF) states. The LF states are antibonding with respect to metal–ligand bonds. Details regarding the time-scale for excited state evolution to the thexi state have only recently become available [138]. McCusker and co-workers performed ultrafast measurements of $\text{Ru}(\text{bpy})_3^{2+}$ in acetonitrile and found that the thexi state is reached within 300 fs at room temperature [138]. Ultrafast dynamics data for other Ru^{II} sensitizers are very sparse at present, which complicates assignments in ultrafast electron injection studies.

Molecular excited states are known to be sensitive to environment and dramatic changes in lifetimes, quantum yields and spectral distribution can arise from so-

Figure 22. Jablonski type diagram for $\text{Ru}(\text{bpy})_3^{2+}$. See text for additional detail.

called ‘rigidochromic’ effects observed when chromophores are constrained in solid-state matrices [139]. Mechanistic information on semiconductor surfaces is difficult to obtain as interfacial electron transfer rapidly depletes the excited states under many conditions. The weak photoluminescence (PL) that remains has been studied by many groups and has been the subject of a recent review [140]. The difficulty with PL measurements, however, is that the observed PL may represent a small fraction of the surface-bound compounds and not the ensemble average.

The work of the groups of Clark, Sutin, Watanabe and Spitler described in Section 1.1 demonstrates convincingly that the efficiency of excited-state electron injection can be controlled by pH [52, 63, 69]. At low pH a sensitized photocurrent was measured but as the pH was raised the photocurrents decreased in a manner consistent with their excited-state reduction potentials [63]. Unfortunately, sensitizers bound to metal oxide surfaces through carboxylate linkages generally desorb rapidly when the pH is raised above 3. An alternative approach for controlling injection yields has been reported by Kelly et al., who found that the efficiency of electron injection for nanocrystalline TiO_2 films of $\text{Ru}(\text{bpy})_2(\text{dcb})^{2+}$ - TiO_2 , immersed in acetonitrile, could be widely ‘tuned’ by varying the electrolyte composition [141]. This finding allowed excited-state behavior to be quantified on semiconductor surfaces.

The excited-state decay kinetics of $\text{Ru}(\text{bpy})_2(\text{dcb})^{2+}$ - TiO_2 immersed in neat acetonitrile, probed by transient absorption spectroscopy, exhibited nonexponential kinetics. By minimizing the excitation irradiance, near exponential kinetics were observed for excited-state decay. However, at high excitation irradiance, second-order kinetics were found to fit the experimental data well. These observations are consistent with competitive first- and second-order processes attributed to radiative and nonradiative excited-state deactivation, Eq. 21, proceeding in parallel with excited-state annihilation, Eq. 22:

A second-order contribution to the excited-state decay of $\text{Ru}(\text{bpy})_3^{2+}$ adsorbed on surfactant- or polymer-modified nanocrystalline TiO_2 films has been reported by Rabani and co-workers [142]. The implied parallel first- and second-order kinetic model has been used successfully to fit many excited-state decays on semiconductor thin films in our laboratory. Energy migration across the nanocrystalline semiconductor surface, like that shown in Figure 23, has been confirmed by co-anchoring an energy transfer trap, $\text{Os}(\text{bpy})_2(\text{dcb})^{2+}$, to the same semiconductor surface [143]. Energy migration, $\text{Ru}(\text{bpy})_2(\text{dcb})^{2+*} + \text{Os}(\text{bpy})_2(\text{dcb})^{2+} \rightarrow \text{Ru}(\text{bpy})_2(\text{dcb})^{2+} + \text{Os}(\text{bpy})_2(\text{dcb})^{2+*}$, occurs with a quantum yield near unity under conditions of suppressed electron injection.

Very little is known about the excited-state properties of *cis*- $\text{Ru}(\text{dcb})_2(\text{NCS})_2$ anchored to semiconductor surfaces. However, the photophysical properties of *cis*- $\text{Ru}(\text{bpy})_2(\text{ina})_2^{2+}$, where ina is isonicotinic acid, 4-COOH-pyridine, on nanocrystalline TiO_2 and ZrO_2 surfaces were recently reported. An intriguing observation was that the activation energy for internal conversion from the thexi state to the ligand field states increased dramatically compared with fluid solution [129]. Similar behavior might be expected for *cis*- $\text{Ru}(\text{dcb})_2(\text{NCS})_2$.

Photoelectrochemistry

Depletion

Conventional models that describe the bias conditions for planar semiconductor–electrolyte junctions are not expected to be applicable to the nanocrystalline semiconductor films. The potential distribution within the complex three-dimensional

Figure 23. Proposal intermolecular energy migration between surface bound sensitizers. Excited states proximate to each other may annihilate and ultimately yield ground state products and heat.

semiconductor network is not well understood and represents a major challenge for future photoelectrochemical research. Below we highlight some significant contributions from theory and from experiments that address basic issues and have implications for the interfacial electron transfer processes relevant to dye sensitization.

For colloidal materials the small size of the semiconductor particles severely restricts the magnitude of the electric field that a particle can support. Albery and Bartlett first considered the potential distribution within spherical semiconductor particles [144]. For large particles, an expression equivalent to that for planar electrodes given in Eq. 6 was derived. For small semiconductor particles the total band bending within the semiconductor, V_b , is limited by the radius r , Eq. 23:

$$V_b = \frac{kT}{6e} \left(\frac{r}{L_D} \right)^2 \quad (23)$$

where L_D is the Debye length given by

$$L_D = \sqrt{\frac{\epsilon_0 \epsilon kT}{2e^2 N_D}} \quad (24)$$

in which these terms have been previously described. The key point is that nanometer-sized semiconductor particles cannot support a large electric field. For example, a 25 nm TiO_2 particle with a relative permittivity of 173 and $N_D = 10^{17} \text{ cm}^{-3}$ is completely depleted at a band bending of only 0.6 meV. Even though the potential drop across an individual particle is small, the average field may still be sufficient to play an important role in dye sensitization processes.

Accumulation and Fermi-level pinning

It has been known for some time that electrochemical, chemical or photoelectrochemical reduction of TiO_2 increases the conductivity, turns the solid blue or black, and the material becomes paramagnetic. The nature of the states created upon reduction has been the subject of much discussion and debate over the years. In 1986, Heller responded to a question by stating that TiO_2 reduction yields a ' Ti^{III} center or "state" that adds an electron to the conduction band. To add an electron the state must be either in the band or close to it' [145]. Today this issue remains very much unchanged and whether reduction yields Ti^{III} states or conduction band electrons is still unknown. How the two can be unambiguously differentiated is also unknown. The issue is important when considering interfacial electron transfer and the nature of the redox active states in TiO_2 . For example, does interfacial electron transfer involve the conduction band continuum or localized redox active $\text{Ti}^{\text{IV/III}}$ states? Some recent literature results that address this issue are described below.

A significant theoretical contribution to the potential distribution within nanocrystalline TiO_2 films was proposed by Rothenberger et al. [146]. These workers employed a Schottky junction model to derive the potential distribution within the TiO_2 particles at negative applied potentials. The model is based on the supposition

Figure 24. Potential distributions of a semiconductor at a) flat band condition, b) accumulation layer, and c) flat band condition with Fermi-level pinning.

that an accumulation layer can be created within each nanocrystalline particle as the potential is shifted negative of the flat-band potential. They demonstrated that an accumulation layer is thinner than a depletion layer when considering cases where the same amount of charge is transferred across the interface. Therefore, in small semiconductor particles an appreciable accumulation layer may be more likely than a depletion layer. Experimentally, a blue–black color, assigned to conduction band and trapped electrons, and a bleach of the UV absorption band, attributed to a Burnstein–Moss shift, were taken as evidence for accumulation layer formation. Spectroelectrochemical analysis in conjunction with this model has been used extensively by Fitzmaurice to calculate flat-band potentials.

Cao et al. reported an alternative Fermi-level pinning model to rationalize the potential distribution at negative applied potentials [147]. They suggested that the reduction of Ti^{IV} surface states to Ti^{III} , observed by low-temperature EPR spectroscopy, pins the Fermi level and, as the potential is raised further, the potential drops across the solution–semiconductor interface.

A simplified description of the limiting Fermi-level pinning and accumulation layer bias conditions is shown in Figure 24. Note that in an accumulation layer the Fermi-level at the surface is above the conduction band edge where free conduction band electrons accumulate. In the Fermi-level pinning model, reduction of the semiconductor, solvent or surface states unpins the band edges and, as E_F is raised further, the potential falls in the Helmholtz layer rather than the semiconductor. In principle, capacitance measurements can be used to characterize an accumulation layer and distinguish it from Fermi-level pinning. The potential dependence of an accumulation layer is given by Eq. 25:

$$C_{\text{SC}} \propto \exp\left(\frac{-eV_b}{2kT}\right) \quad (25)$$

For nanocrystalline TiO_2 films, the 120 mV per decade predicted by Eq. 25 was not realized by Cao et al. [143]. Instead ~ 360 mV per decade was measured, consistent

with a significant fraction of the applied potential falling across the Helmholtz layer. Zaban et al. also found that capacitance data were inconsistent with accumulation layer formation in sol–gel processed TiO₂ [148].

The electrochemical reduction of TiO₂ is known to be accompanied by the intercalation of small cations. This finding has been explored in sensitizing anatase films for battery applications [149]. Cation coordination to titanium alkoxide sol–gel precursors is also well known [150]. Lyon and Hupp used quartz crystal microbalance techniques to determine the mass of intercalating cations as the TiO₂ film is reduced [151]. Hagfeldt and co-workers have studied Li⁺ and Na⁺ intercalation into anatase TiO₂ both theoretically and experimentally [152, 153]. They found that the diffusion constants for Li⁺ and Na⁺ are temperature dependent with an activation barrier of 0.4 eV for insertion and 0.5 eV for extraction. The Li⁺ diffusion coefficient at 25 °C into the nanoporous structure was approximately $2 \times 10^{-17} \text{ cm}^2 \text{ s}^{-1}$ for insertion and $4 \times 10^{-17} \text{ cm}^2 \text{ s}^{-1}$ for extraction.

The issue of how to characterize reduced TiO₂ and the role of intercalation are still under much debate in the literature. In the dye-sensitized electrode field, the term ‘accumulation’ is used very loosely. Many authors use the term accumulation layer when they actually mean an increased concentration of trapped electrons. This language is unfortunate, as accumulation layers have well defined meanings in solid-state semiconductor devices. It is unclear what accumulated trapped electrons really means.

Photocurrent–voltage behavior

The state of the art regenerative solar cell consists of the sensitizer *cis*-Ru(dcb)₂(NCS)₂ anchored to colloidal anatase TiO₂ films with an I[−]I₂ organic electrolyte. An *i*–*V* curve recorded with 1000 W m^{−2} of air mass 1.5 illumination at 25 °C is shown in Figure 25 [154]. From these data, a *V*_{oc} of 0.79 V, an *i*_{sc} of 4.83 mA, a fill factor of 0.71 and an η_{max} of 0.11 were obtained. The active area of the electrode was kept low, 0.249 cm², to minimize resistive losses associated with the tin oxide glass and the nanocrystalline semiconductor film. The power efficiency was not significantly changed when the temperature was raised from 20 to 60 °C.

Photocurrent efficiencies near unity have been measured at single wavelengths for a wide variety of organic and inorganic sensitizers [119]. To circumvent the difficulty of correcting for transmitted light, the term incident photon-to-current efficiency (IPCE) has emerged. IPCE values are a lower limit of the actual photocurrent quantum yield of a sensitized cell. An experimentally useful expression for the determination of IPCE in photoaction spectra is

$$\text{IPCE} = \frac{(1240 \text{ eV nm})[\text{photocurrent density } (\mu\text{A cm}^{-2})]}{[\text{wavelength (nm)}][\text{irradiance } (\mu\text{W cm}^{-2})]} \quad (26)$$

The IPCE of sensitized electrodes is wavelength dependent. Occasionally, the IPCE is given as a percentage rather than a fraction from 0 to 1. In this case, an IPCE % of 80 % is equivalent to an IPCE of 0.8, and indicates that 80 of 100 incident photons are converted to electrons in the external circuit. It is important to distinguish

Figure 25. A typical i-V curve recorded with 1000 W/m^2 of air mass 1.5 illumination at 25°C for a regenerative solar cell based on *cis*-Ru(dcb)₂(NCS)₂/TiO₂.

between IPCE measurements made at a single wavelength and global efficiencies measured under sunlight or simulated sunlight conditions.

In most cases, the photoaction spectrum is coincident with the absorbance spectrum of the surface bound sensitizer, for all but one case. Assuming Beer's law is applicable, the LHE can be related to the molar extinction coefficient by

$$\alpha(\lambda) \equiv \text{LHE}(\lambda) = 1 - 10^{-[1000(\text{cm}^3 \text{ L}^{-1})\varepsilon(\text{mol}^{-1} \text{ L cm}^{-1})\Gamma(\text{mol cm}^{-2})]} \quad (27)$$

where ε is the molar extinction coefficient at wavelength λ and Γ is the surface coverage in mol cm^{-2} [33]. For thick films of sensitizers on planar surfaces or under conditions where species in the electrolyte absorb light, inner filter effects and competitive light absorption can also affect the shape of the photocurrent action spectrum.

The IPCE measured at a single wavelength of light is the product of three terms:

$$\text{IPCE} = (\text{LHE})(\phi)(\eta) \quad (28)$$

where ϕ is the quantum yield for electron injection and η is the efficiency with which the injected carriers reach the external circuit. Obviously, if either of the two terms is wavelength dependent, then the shape of a photoaction spectrum will change from that predicted solely on the absorbance spectrum. At the time of writing, there is only one example of a sensitizer whose absorption spectrum clearly does not match the photoaction spectrum. This sensitizer is $\text{Fe(dcb)}_2(\text{CN})_2$ and the importance of this observation is described in Section 1.2.2. By defining the absorbed photon to current efficiency (APCE) as IPCE/LHE , any wavelength dependence can be attributed to changes in ϕ and/or η .

Models for the photoelectrochemical behavior of colloidal semiconductor films have been described by Lindquist and co-workers [155]. Beginning with Gartner's model, a simple expression was derived:

$$\phi_{\text{FS}} = \frac{L}{d} (\phi_{\text{BS, max}}) \quad (29)$$

where ϕ_{FS} is the quantum efficiency for front side illumination, $\phi_{\text{BS, max}}$ is the quantum efficiency for back-side illumination, L is the electron diffusion length and d is the film thickness. This expression was derived assuming that (1) electron transport occurs by diffusion and (2) the diffusion length of the electron in the semiconductor is constant. With this equation, using front- and back-side illumination of sensitized films of known thickness, a diffusion length of 0.8–0.9 μm was calculated.

The shape of the i - V curve was predicted to follow Eq. 30:

$$I = I_{\text{L}} - I_{\text{S}}(e^{qv/kTm} - 1) \quad (30)$$

where I_{L} is the photocurrent, I_{S} is the saturation current, m is the ideality factor and the other terms have been described previously. With an ideality factor of 2.1, this expression accurately models the i - V behavior over a four-fold change in incident irradiance.

Carrier transport

A fascinating aspect of the sensitized colloidal semiconductor films is that injected electrons created throughout the semiconductor network are collected in the external circuit with high efficiency. This implies that carrier transport through the ~ 10 μm thick film occurs with no measurable recombination loss. The mechanisms of carrier transport have been studied in some detail. Carrier transport in a semiconductor film can be described by the continuity equation [155]:

$$\frac{\partial n}{\partial t} = \frac{1}{e} \frac{\partial J}{\partial x} + G - R \quad (31)$$

where n is the electron density under illumination, J is the current density in the film and G and R are the carrier generation rate and recombination rate, respectively. Recombination is assumed to be proportional to the electron concentration and can be written as $R = (n - n_0)/\tau_0$, where n_0 is the electron density in the dark and τ_0 is the position-independent electron lifetime. Both electron drift and diffusion can contribute to the current density:

$$J = en\mu_n \frac{\partial \phi_{\text{sc}}}{\partial x} + eD \frac{\partial n}{\partial x} \quad (32)$$

where μ_n is the electron mobility and D is the diffusion coefficient of the electron. Since the TiO_2 particles are too small to sustain significant band bending, the current density is dominated by the diffusion term. In the absence of migration, the continuity equation is given by

$$D \frac{\partial^2 n(x, t)}{\partial x^2} - \frac{\partial n(x, t)}{\partial t} - \frac{n(x, t) - n_0}{\tau_0} + \Gamma \alpha \exp(-\alpha x) = 0 \quad (33)$$

The first two terms represent the electron flux and the change in electron concentration with time, respectively. The third term represents the recombination rate and is assumed to be first order with electron density. The fourth term is the generation term that assumes the dye concentration is uniform throughout the film. Eq. 33 has been solved analytically. Södergren and co-workers [155] have shown that the steady-state photocurrent is consistent with this model and the assumption that electron transport occurs by diffusion.

The first time-resolved photocurrent measurements were employed by Schwarzbarg and Willig [156], who used Shockley–Reed kinetics to simulate their data numerically. Later, Cao et al. reported the first transient photocurrent measurements obtained in the frequency domain, using intensity-modulated photocurrent spectroscopy (IMPS), and compared them with data acquired in the time domain [157]. A characteristic feature of dye-sensitized nanocrystalline TiO_2 cells was the appearance of slow photocurrent transients that gave rise times varying from milliseconds to seconds depending on the experimental conditions. Several considerations led to the conclusion that the slow response was due to the transport of electrons in the semiconductor. First, the rate of excited-state electron transfer to the semiconductor was known to be at least six orders of magnitude faster. Second, sensitizer regeneration by the iodide electrolyte was known to occur rapidly and to contribute only to the observed transients at low concentrations or high irradiance. Therefore, the sluggish photocurrent transients are reasonably attributed to slow carrier transport. The apparent diffusion constants cannot correspond to the transport of free electrons in the conduction band of single-crystal rutile TiO_2 . Based on an electron mobility of about $1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, the diffusion coefficient for free CB electrons determined from the Einstein equation is of the order of $10^{-2} \text{ cm}^2 \text{ s}^{-1}$ at room temperature. This value is much larger than what could be inferred from the transient photocurrent data.

The results imply that the diffusion coefficient represents the thermally activated transport of electrons through the particle network. Indeed, these and subsequent studies have been interpreted with models that involve trapping of conduction band electrons or electron hopping between trap sites [158, 159]. An unexpected feature of the diffusion constants reported by Cao et al. is that they are dependent on the incident irradiance. The photocurrent rise times display a power law dependence on light intensity with a slope of -0.7 . The data could be simulated if the diffusion constant was assumed to be second order in the electron concentration, $D \propto n^2$. The molecular origin of this behavior is not well understood and continues to be an active area of study [157, 159].

Open-circuit photovoltage

Since the nanocrystalline semiconductor particles are not expected to support large depletion layers, the origin of the 600–800 mV open-circuit photovoltage, V_{oc} , has been the subject of much discussion. Neglecting the contacts and leads, V_{oc} is de-

terminated by the difference in Fermi energies of the two current collectors. These are usually the tin oxide glass substrate of the sol–gel processed electrode and platinum at the counter electrode. V_{oc} represents the maximum Gibbs free energy a regenerative solar cell can produce under conditions of constant irradiance [160].

In a conventional single crystal or polycrystalline photoelectrochemical cells, the difference between the Fermi level of the semiconductor electrode and the counter electrode is expected to follow a logarithmic relationship with the light intensity described by the diode equation [160]. An analog of the diode equation for dye-sensitized cells can be obtained by equating the recombination rate to the injection flux under open-circuit conditions, Eq. 34:

$$V_{oc} = \frac{kT}{e} \ln \left(\frac{I_{inj}}{n_{s0} k_{et} N_{ox}} \right) \quad (34)$$

where N_{ox} is the concentration of the oxidized donor species, k_{et} is the rate constant for reduction by electrons in the TiO_2 , n_{s0} is the electron concentration in the dark and I_{inj} is the electron injection flux from the dye under illumination. Implicit in this equation is that the injection of charge carriers decreases the band bending in the space-charge layer and thus raises the Fermi level of the semiconductor electrode according to the Boltzmann equation [161]. For regenerative solar cells based on these nanocrystalline materials, V_{oc} increases exponentially with light intensity with a slope typically of the order of 100–120 mV per decade (i.e., an ideality factor of 1.5–2.5), suggesting that the diode equation captures the essential physics of the device [155].

Grätzel and co-workers first reported that treating the sensitized electrode with 4-*tert*-butylpyridine increased the open-circuit photovoltage by 200–300 mV without significantly altering the short-circuit photocurrent [161]. With Eq. 34, a 5.5×10^4 -fold decrease in the rate constant for the reduction of triiodide by electrons in TiO_2 was calculated. Frank and co-workers also observed increased V_{oc} on treating their sensitized electrodes with pyridine derivatives and pointed out that band edge shifts could also account for the effect [162].

Band edge positions

At present there is no unambiguous method for determining the energetic position of the conduction band edge of nanocrystalline semiconductor films under experimental conditions relevant to dye sensitization. Clearly, the lack of a depletion layer precludes traditional capacitance measurements with Mott–Schottky analysis described in Section 1.1. The onset of photocurrents in photocurrent–voltage plots can provide a crude working estimate under some conditions, but is problematic for the reasons described previously. This is unfortunate as accurate energetics are necessary to compare experimental results with even the simplest theory [4].

Fitzmaurice and co-workers have pioneered the use of spectroelectrochemical data to quantify flat-band potentials under a variety of conditions [163–167]. Table 2 gives data measured in the indicated solvents. Flat-band potentials for different cations and mixed solvents are also available in the literature. With this spectro-

Table 2. Flat-band potential (V_{fb}/V vs. SCE) of nanocrystalline TiO_2 films determined by spectroelectrochemistry^{a,b}.

EC	−1.59		

^a MeCN = acetonitrile; EtOH = ethanol; MeOH = methanol; DMF = dimethylformamide; THF = tetrahydrofuran; EC = ethylene carbonate. For all experiments, electrolyte is 0.2 M tetrabutylammonium perchlorate.

^b Data obtained from (a) Enright, B.; Redmond, G.; Fitzmaurice, D. *J. Phys. Chem.* **1994**, 98, 6195; (b) Redmond, G.; Fitzmaurice, D. *J. Phys. Chem.* **1993**, 97, 1426.

electrochemical approach, the flat-band potential shift the expected 59 mV per pH unit expected for metal oxide semiconductors. The potential calculated in 1.0 M LiClO₄ acetonitrile is very close to the Ti(IV/III) reduction potential, −1.0 V vs. SCE, measured by cyclic voltammetry of chemically vapor-deposited anatase films in the same electrolyte [153b,c]. Furthermore, the model predicts that electron injection from excited sensitizer should not occur in tetrabutylammonium perchlorate–acetonitrile and, at least in one case, this has been observed. Therefore, there is some reason to be optimistic that the tabulated values, or at least the trends, will be applicable to regenerative solar cells.

The accumulation layer model used to calculate the flat-band potentials with spectroelectrochemical data has been described above. Much like the difficulties of extrapolating flat-band potentials from conditions of strong depletion (i.e., Mott–Schottky analysis), extrapolation from strongly reducing conditions is also subject to systematic bias. Flat-band potentials are not singular parameters and there is no guarantee that the band edges will remain fixed as the Fermi level is lowered. Any degree of band edge unpinning will shift the tabulated potentials further in the negative direction, so the values listed are, perhaps, best thought of as lower limits for dye sensitization studies.

2.2.2 Examples of Interfacial Electron Transfer at Colloidal Semiconductor Electrodes

Nanocrystalline semiconductor films can be prepared with high transparency in the visible region [112]. This feature allows excited states and electron transfer to be characterized in considerable molecular detail by transmission-based spectroscopic

methods in addition to the more conventional photoelectrochemical techniques. In this final section we focus specifically on charge injection and recombination across molecular sensitizer–semiconductor interfaces quantified by direct spectroscopic techniques. The iodide redox chemistry critical for sensitizer regeneration and high conversion efficiencies is not well understood and will not be reviewed here [168–171]. The growing area of semiconductor sensitization by small band-gap semiconductors is also not included [172–174].

Table 3 gives a summary of the interfacial charge injection and recombination rate constants determined by direct spectroscopic techniques. The data are not directly comparable as different TiO_2 preparations, solvents, electrolytes, time-scales and kinetic models were used by different experimentalists. Nevertheless, the table demonstrates the wide range of sensitized materials reported in the literature and provides a basis for further discussion.

A key to the high energy conversion efficiencies of sensitized nanocrystalline semiconductors is that the rate of charge injection is orders of magnitude faster than is charge recombination. Why this fortuitous difference in rate constants exists has been the subject of much discussion. Shown schematically in Figure 26 are simplified models that are often invoked. For metal-to-ligand charge transfer (MLCT) excited states, electron injection is formally from a reduced ligand (typically dcb^-) and recombination is to the d-orbitals of the metal. On the semiconductor side, electron injection into a conduction band continuum followed by thermalization and/or trapping is generally proposed to precede recombination. Alternatively, injection and recombination may involve a well defined surface state and $\text{Ti}^{\text{IV/III}}$ redox chemistry. In any event, different molecular orbitals are involved in the electron injection and recombination processes. Furthermore, there is strong evidence that charge injection is activationless whereas charge recombination falls in the Marcus kinetic inverted region. Under some conditions charge recombination is sluggish because the injected electron is translated away from the oxidized sensitizer and electron transfer becomes rate-limited by diffusion back to the oxidized sensitizer. Other data suggest that proton-coupled electron transfer is important in controlling charge recombination rates. The experimental studies discussed below seek to develop a deeper understanding of these important interfacial electron transfer processes. The perfect portrait will emerge from the continued studies of many excellent research groups around the world.

Electron injection kinetics

The excited sensitizer that injects an electron into the semiconductor may be in either an equilibrated singlet or triplet ('thexi') states or a vibrationally 'hot' excited state. For organic chromophores, the singlet and triplet states are well defined and can be observed by many techniques such as fluorescence or low-temperature phosphorescence, respectively [9, 10]. For the excited states of second- and third-row transition metal compounds, spin is not a good quantum number [137]. The large metal center imparts significant spin–orbit coupling and emissive excited states generally possess both singlet and triplet character [137]. The nature of the injecting excited states for Ru^{II} compounds is discussed in the next section.

Table 3. Summary of electron transfer rate constants between sensitizer and semiconductor.

Singlet and triplet excited state injection

Moser and Grätzel [186] described the dynamics of charge injection and recombination with eosin Y on $\sim 50 \text{ \AA}$ colloidal TiO_2 particles in aqueous solution. The triplet state of eosin decays with the same kinetics in free solution and when associated with TiO_2 , indicating that interfacial charge separation does not occur from the triplet state [186]. Rather, electron injection occurs from the singlet excited state. Time-resolved resonance Raman studies demonstrate the presence of the oxidized eosin and revealed significant surface-sensitizer interactions [199]. At pH 3, the quantum yield for charge separation was estimated to be 0.4 with rate constant $8.5 \times 10^8 \text{ s}^{-1}$. It was found that recovery of the oxidized eosin sensitizer, EO^+ , followed complex kinetics. Kinetic analysis with some assumptions yields a charge recombination rate of $2 \times 10^5 \text{ s}^{-1}$ and the mean lifetime of interfacial charge separated states is $\sim 5 \text{ \mu s}$. More recent picosecond studies have placed the charge separation rate at $k_{inj} = 9.5 \times 10^8 \text{ s}^{-1}$ [200].

Willig and co-workers time-resolved the rate of electron injection from a perylene derivative that contained a phosphonate functional group and two *tert*-butyl groups [192]. The phosphonate was used for binding to nanocrystalline TiO_2 thin films and the bulky organic groups were designed to prevent perylene association. A rough estimate of the excited-state donor levels of perylene relative to the E_{CB} indicated that the injection process should be activationless. Interfacial electron injection was probed with femtosecond resolution in ultra-high vacuum via transient absorption and fluorescence up-conversion techniques. Identical time constants were observed for the decay of the excited state and the formation of the oxidized perylene. A temperature-independent (300–22 K) 190 fs dominant fast rise time was measured, consistent with activationless electron injection.

Kamat and Patrick have shown that dynamic quenching by wide band-gap semiconductors does occur under some conditions [201]. Thionine was used to sensitize 20–40 \AA ZnO colloids. Both the ZnO particles and the thionine sensitizers were

Figure 27. Chem 3-D minimized structure of *cis*-Ru(dcb)₂(NCS)₂. This sensitizer is referred to as N3 since it was the third dye prepared by Nazeeruddin.

positively charged, precluding significant ground-state interactions. Therefore, the luminescence and absorption properties of thionine were not significantly altered by exposure to ZnO. In contrast, the lifetime of the thionine triplet excited state decreased from 88 to 15 μ s as the concentration of ZnO colloid was increased and the appearance of the oxidized sensitizer demonstrated an electron transfer mechanism that proceeds with a quantum yield of 0.1. Grätzel and co-workers also concluded that copper 2- α -oxymesoisochlorin *e*₄ injects electrons into anatase TiO₂ thin films from the triplet state with a rate constant $k_{inj} = 3 \times 10^8 \text{ s}^{-1}$ [181].

'Hot' electron injection

Femtosecond absorption studies of *cis*-Ru(dcb)₂(NCS)₂ anchored to a mesoporous nanocrystalline TiO₂ thin films, shown schematically in Figure 27 and abbreviated *cis*-Ru(dcb)₂(NCS)₂-TiO₂, have recently been reported by several groups [195, 196, 202]. In these sensitized materials a direct electron transfer pathway from the Ru(II) metal center to the semiconductor is reasonably ruled out based on comparisons of the solution and semiconductor bound absorption spectra of *cis*-Ru(dcb)₂(NCS)₂ that are reported to be the same within experimental error. We note that direct charge transfer from inorganic sensitizers with ambidentate cyano ligands [127, 190, 203, 204] or organic chelates [205–207] is well known and the subject of intense research.

Durrant and co-workers performed ultra-fast interfacial electron injection studies with *cis*-Ru(dcb)₂(NCS)₂-TiO₂ in 1:1 ethylene carbonate–propylene carbonate solvent and were able to observe both the oxidized sensitizer and the electron in TiO₂ by time-resolved absorption spectroscopy [202]. Unfortunately, at long observation wavelengths, $\lambda = 650\text{--}900 \text{ nm}$, these absorption features overlapped with each other, making assignments and analysis difficult. Detailed analysis of the transient absorption data indicate that the electron injection process is at least bi-phasic with $\sim 50\%$ injecting in less than 150 fs and 50 % in 1.2 ps.

Willig and co-workers used near-infrared spectroscopy to measure excited-state interfacial electron transfer rates after pulsed light excitation of *cis*-Ru(dcb)₂(NCS)₂-TiO₂ in vacuum from 20 to 295 K [208]. They reported that excited-state electron injection occurred in less than 25 fs, prior to the redistribution of the excited-state vibrational energy, and that the classical Gerischer model for electron injection was inappropriate for this process. They concluded that the injection reaction is controlled by the electronic tunneling barrier and by the escape of the initially prepared wave packet describing the hot electron from the reaction distance of the oxidized dye molecule. It appears that some sensitizer decomposition occurred in these studies as the transient spectrum was reported to be similar to that of the thermal oxidation product of *cis*-Ru(dcb)₂(NCS)₂.

Lian and co-workers reported the femtosecond mid-IR properties of *cis*-Ru(dcb)₂(NCS)₂ in fluid ethanol solution and when anchored to nanocrystalline Al₂O₃ and TiO₂ thin films [195]. In this spectral window, the asymmetric and symmetric stretches of the thiocyanate ligands absorb strongly and serve as a marker for the ground, excited and oxidized states. In addition, the injected electron appears as a broad positive absorption band in this spectral range. Instrument response-limited excited-state formation, Ru^{III}(dcb⁻)(dcb)(NCS)*, was observed in ethanol. Excitation of *cis*-Ru(dcb)₂(NCS)₂-TiO₂ led to the appearance of a broad absorption assigned to the electron in TiO₂. The rise time was fitted to a biexponential model with a fast 50 ± 25 fs rate that comprised about 84 % of the signal and a slower 1.5 ± 0.5 ps component that accounted for the other 16 %. The fast component was assigned to the electron injection process. Because the signature of the slower component was sample dependent, its origin was less certain. These results were in general agreement with the previous studies by Durrant and co-workers. However, the results do not provide compelling evidence for injection from vibrationally hot excited states as suggested by Willig and co-workers.

Spectroscopic evidence for electron injection from ‘hot’ vibrational states came from the work of Moser and Grätzel [209]. They employed time-resolved absorption spectroscopy to quantify the injection yields of *cis*-Ru(dcb)₂(NCS)₂-TiO₂ and *cis*-Ru(dcb)₂(NCS)₂-Nb₂O₅ as a function of excitation wavelength. For TiO₂, the injection yield was found to be unity and independent of excitation wavelength within experimental error. In contrast, the quantum yield for injection on Nb₂O₅ dropped from 0.5 at 450 nm to ~0 at 640 nm. An alternative Ru^{II} sensitizer with a lower lying thexi state was found to give wavelength-dependent electron injection on anatase TiO₂. If injection occurred from the thexi state, the yield would be independent of excitation wavelength, contrary to what is observed. The authors concluded that injection occurs from a single state. Injection was modeled by Fermi’s Golden rule for non-adiabatic electron transfer:

$$k_{\text{inj}} = \frac{2\pi}{\hbar} |H|^2 \frac{1}{\hbar\omega} \quad (35)$$

By assuming $\omega = 1500 \text{ cm}^{-1}$ and an injection rate of $8 \times 10^{12} \text{ s}^{-1}$, an electronic coupling matrix element $H = 100 \text{ cm}^{-1}$ was estimated for injection from *cis*-Ru(dcb)₂(NCS)₂* to TiO₂.

Figure 28. Strong evidence for hot interfacial electron injection. Nb_2O_5 has more negative conduction band edge and energetically requires a more potent reducing agent for electron injection. Blue light ($\lambda = 450 \text{ nm}$) excitation provides efficient sensitization of Nb_2O_5 while red light ($\lambda = 650 \text{ nm}$) does not.

The identification of electron injection as an ultra-fast process indicates that sensitizers with short excited-state lifetimes should be useful for energy conversion, provided that the transient spectroscopic data is at all relevant to the solar cell. Ferrere and Gregg have in fact reported sustained photocurrents from *cis*- $\text{Fe}(\text{dcb})_2(\text{CN})_2$ - TiO_2 thin films in regenerative solar cells [210]. By analogy with related iron polypyridyl compounds, this sensitizer's MLCT excited states are very short lived owing to rapid population of ligand field states. The fact that a sustained photocurrent is measured with this compound indicates that injection must also be very fast in the operational solar cell. A comparison of the solution absorption and photoaction spectra revealed evidence for preferential injection yields from 'upper' excited states as is shown in Figure 28 [210]. If 'hot' injection is commonplace in these materials, it is surprising that it does not manifest itself more often in photoaction spectra like this.

Manipulation of semiconductor-sensitizer energetics

Several reports have addressed how interfacial electron transfer rate constants vary with thermodynamic driving force. The driving force is tuned by manipulating the conduction band edge through adsorption of specific cations, utilizing different semiconductors, or by keeping the semiconductor constant with a series of sensitizers with known formal potentials. A difficulty in these studies is that the position

Figure 29. Absorption (solid line) and photoaction (dashed line) of *cis*-Fe(dcb)₂(CN)₂ adsorbed onto a nanocrystalline TiO₂ thin film.

of the band edges is not known precisely, nor are the formal potentials of the surface-bound sensitizers. One therefore hopes that solution electrochemical data translate directly to the sensitized interface so that trends and 'apparent' driving forces can be estimated [136]. These studies are important for the development of mechanistic descriptions of dye sensitization mechanisms and interfacial electron transfer.

Proton- and cation-induced shifts

Proton adsorption/desorption was utilized by Clark and Sutin to control electron injection yields and probe Gerisher's distributions at planar rutile electrodes. More recently, Grätzel and co-workers found that excited-state electron injection from tetrakis(4-carboxyphenyl)porphyrinato]Zn^{II} to colloidal TiO₂ particles was negligible at pH > 8 but increased substantially when the pH was lowered [211]. However, in this case it was difficult to rule out a trivial mechanism where the sensitizer simply desorbed from the surface at higher pH.

Yan and Hupp used nanosecond transient absorption to probe charge recombination after selective excitation of a hexaphosphonated Ru(bpy)₃²⁺ derivative bound to DeGussa TiO₂ as a function of pH [212]. They found that a fast first-order charge recombination process was insensitive to pH over 13 decades of H⁺ concentration. Assuming the sensitizer oxidation potential is independent of pH and

that electron transfer occurs from a TiO_2 donor state that displays the expected 59 mV per pH unit dependence, the driving force for charge recombination should have been varied by over 470 mV, yet there was no observed change in the measured rate constants. The authors suggested two possible explanations for this surprising lack of pH sensitivity. First, charge recombination occurred from a surface state with a pH-independent potential. Alternatively, proton-coupled back electron transfer occurred, where the rate-determining electron transfer preceded H^+ transfer, such that the kinetically relevant driving force was different from the overall reaction driving force. Based on previous work with sensitized rutile TiO_2 , it is surprising that the excited sensitizer injects electrons into TiO_2 over such a broad pH range and suggests that localized surface states play a key role.

Kelly et al. found that increasing the concentration of LiClO_4 in an acetonitrile electrolyte surrounding a *cis*- $\text{Ru}(\text{bpy})_2(\text{dcb})$ - TiO_2 film results in an enhancement of the interfacial electron injection yield [141]. Remarkably, the injection quantum yield could be reversibly controlled from below detection limits to near unity simply by varying the Li^+ concentration. Other alkali and alkaline earth metal cations were found to exhibit a similar effect, but at a magnitude related to the charge-to-radius ratio of the cation. The quantum yield for electron injection increased approximately with $\log[\text{Li}^+]$. The recombination of the injected electron with the oxidized sensitizer was fitted to a second-order kinetic model and the rate constants were independent of the Li^+ concentration. This Li^+ concentration range would correspond to an approximately 1 eV change in driving force based on spectroelectrochemical data (Table 2). However, there was no change in the measured rate constants or evidence for screening of the injected electron under these conditions.

Figure 30. Proposed energy diagram showing the proposed mechanism for $[\text{Li}^+]$ enhancement of the injection yield for $\text{Ru}(\text{dcb})(\text{bpy})_2^{2+}/\text{TiO}_2$. Li^+ adsorption lowers the acceptor states of TiO_2 which results in energetically more favorable excited state injection.

Interestingly, the excited-state quenching with lithium cations was a static process [141]. If electron injection were occurring from the thexi state, one would expect the lifetime to decrease to $1/k_{\text{inj}}$, contrary to what was observed. One explanation is that only the sensitizers proximate to lithium adsorption sites are able to inject and surface heterogeneity underlies the largely static process. This explanation was not favored as efficient energy migration across the surface was known to occur and this same process should lead to sensitizers ‘finding’ an injection site. An alternative explanation is that the thexi state is thermodynamically unable to inject electrons. The conduction band edge position, estimated from spectroelectrochemical data in Table 2, is in fact midway between the Franck–Condon and the thexi states. Injection then is competitive with vibrational relaxation and the thexi state lifetime would not be quenched by electron injection as is observed. If this interpretation is correct it calls into question the common approach of using time-resolved photoluminescence data to estimate electron injection rate constants.

Qu et al. reported that *cis*-Ru(bpy)₂(ina)₂(PF₆)₂, where bpy is 2,2′-bipyridine and ina is isonicotinic acid, anchored to colloidal TiO₂ thin films displays injection yields that can be controlled with temperature and ionic strength [129]. The chromophoric bipyridine ligands do not bind directly to the semiconductor surface, so excited-state injection occurred by a remote process. The interfacial electron injection yields were measured by comparative actinometry. In 0.1 M LiClO₄–acetonitrile at 0 °C, the injection yield was unity, but decreased to 0.5 at room temperature. The injection quantum yield could be reversibly tuned between these extremes or to intermediate values by controlling the temperature. Photophysical properties of *cis*-Ru(bpy)₂(ina)₂(PF₆)₂ bound to TiO₂ and to insulating ZrO₂ samples led to the proposed excited-state deactivation routes shown in Figure 31.

Figure 31. Jablonski type diagram invoked to rationalize the origin of temperature dependent injection quantum yield for *cis*-Ru(pby)₂(ina)₂²⁺ on TiO₂.

Temperature-dependent injection was attributed to a competitive population of low-lying state [thought to be a ligand field (LF) state] and the remote injection process. Regardless of the mechanism, the results demonstrate that sensitized electrodes can be fabricated for temperature-sensing applications.

Semiconductor-induced shifts

Fessenden and Kamat examined the photoluminescence and microwave conductivity properties of $\text{Ru}(\text{dcb})(\text{bpy})_2^{2+}$ anchored to colloidal ZnO , TiO_2 and SnO_2 films and estimated the electron injection rate constant from the data [194]. The energetics of the conduction band edge, E_{CB} , at pH 1 follows the trend $\text{SnO}_2 > \text{ZnO} > \text{TiO}_2$. PL decays at 650 nm were modeled as a biexponential decay, with an approximate order of magnitude difference between the fast and slow rates. Following selective excitation of the sensitizers, direct evidence for electron injection came from an absorption growth in the microwave region assigned to conduction band electrons. For SnO_2 and ZnO , the microwave kinetics agreed well with the electron injection rates from PL quenching measurements. The electron transfer rates calculated from these data, $k_{\text{inj}} = (1-3) \times 10^8 \text{ s}^{-1}$, showed an interesting correlation with the energy difference between the sensitizer excited-state oxidation potential and the energy of the semiconductor conduction band edge, ΔE (Figure 32). The rate was found to increase with ΔE . A similar behavior had previously been observed for $\text{Ru}(\text{bpy})_3^{2+}$ adsorbed in semiconductor powders [213]. In fact, the raw experimental data reflect this and the larger is ΔE the faster the PL decays to baseline. An implication of these observations, and one possible interpretation, is that the semiconductor density of unfilled states increases significantly at more negative potentials (closer to the vacuum level) resulting in better overlap with the excited sensitizer donor levels.

Charge recombination

Hupp and co-workers [214] studied interfacial charge recombination as a function of the driving force in considerable detail. Early work focused on ferrous cyano

Figure 32. The relative energetic positions of semiconductor conduction band edges, E_{CB} , for SnO_2 , ZnO , and TiO_2 relative to a sensitizer excited state, S^* . ΔE is the apparent energy separation between the conduction band edge and the excited state sensitizers' reduction potential.

compounds bound to TiO_2 colloids through the ambidentate cyanide ligands. This interaction gives rise to direct interfacial intervalence charge-transfer bands in the visible region, i.e., $\text{Fe}^{\text{II}}-\text{CN}-\text{Ti}^{\text{IV}} \rightarrow \text{Fe}^{\text{III}}-\text{CN}-\text{Ti}^{\text{III}}$. A series of $\text{Fe}(\text{CN})_5\text{X}^{n-}$ compounds were prepared with known $\text{Fe}^{\text{III/II}}$ potentials [214]. The first-order rate constant for charge recombination was quantified by nanosecond absorption spectroscopy and found to decrease with increased driving force, thereby providing strong evidence for Marcus inverted kinetic behavior.

More recently, Dang and Hupp reported charge recombination studies for ruthenium tris(polypyridine) compounds electrostatically bound to tin oxide colloids [215]. Again, inverted behavior was observed and charge recombination rate constants decreased with driving force. Back electron transfer was also shown to be thermally activated consistent with the contention that variations in the Franck–Condon factors, and not the electronic coupling, are responsible for the inverted behavior. Hartland and co-workers also concluded that back electron transfer from TiO_2 colloids to oxidized anthracene isomers was inverted [178]. However, the inverted behavior stands in apparent conflict with the pH studies described above and other driving force studies performed at sensitized TiO_2 interfaces in water. Dang and Hupp speculated that this difference arises from localized $\text{Ti}^{\text{III/IV}}$ behavior and sequential electron transfer–proton transfer reaction sequences.

Moser and Grätzel reported temperature-dependent data for charge recombination from colloidal anatase TiO_2 particles to the cation radicals of three different sensitizers, alizarin, a merocyanin dye and a coumarin dye [216]. Although these reactions were believed to fall deep into the Marcus inverted region, they showed practically no activation energy. The largest temperature dependence was observed for alizarin, which showed an increase by only about a factor of 10 over a 200°C temperature change. The results were interpreted in terms of a quantum mechanical model for nonadiabatic electron transfer.

Hasselmann and Meyer prepared a series of Re^{I} coordination compounds, *fac*- $\text{Re}(\text{deeb})(\text{CO})_3(\text{X})$, where (deeb) is 4,4'-(COOEt)₂-2,2'-bipyridine and X is I^- , Br^- , Cl^- or CN^- , and [*fac*- $\text{Re}(\text{deeb})(\text{CO})_3(\text{py})$](OTf), where OTf^- is triflate anion and py is pyridine, specifically to probe charge recombination kinetics in colloidal TiO_2 films in 1.0 M LiClO_4 –acetonitrile solution at 22°C [217]. Recombination of the electron in TiO_2 with the oxidized sensitizer required milliseconds for completion and was quantified on a 10^{-7} – 10^{-3} s time-scale. Charge recombination kinetic rate constants were insensitive to an ~ 960 mV change in the apparent driving force, the sensitizer molecular geometry, the identity of the metal (Re, Ru or Os) and the number of carboxylic acid groups (two or four) present. The insensitivity to these factors suggested that interfacial electron transfer was not rate limiting. The authors speculated that charge recombination was limited by diffusional encounters of the injected electron and oxidized sensitizer under these conditions [217].

Effects of applied potential

The first transient absorption measurements of dye-sensitized nanocrystalline thin films under an external bias were carried out by O'Regan et al. [112]. These authors

followed the absorbance change at 480 nm following nanosecond pulsed excitation of Ru(dcb)_3^{2+} - TiO_2 films immersed in aqueous 0.2 M LiClO_4 at pH 3. The film was externally biased over the range -0.8 to 0.6 V vs. SCE. At negative applied bias, the excited state was found to luminesce strongly and current generation was near zero. Positively biasing the electrode resulted in quenching of the luminescence and optimized photocurrent generation. Transient absorption measurements over the potential range examined demonstrated a rapid loss of the Ru^{II} precursor that could not be time resolved from the laser pulse. The rapid formation of the transient signal was attributed to electron injection, $k_{\text{inj}} > 10^8 \text{ s}^{-1}$. At -0.45 V vs. SCE, the recovery of the ground state proceeds with a rate constant of $1.5 \times 10^6 \text{ s}^{-1}$, similar to that for excited-state decay of the complex in solution.

Kamat and co-workers studied electron injection following excitation of $\text{Ru(bpy)}_2(\text{dcb})^{2+}$ on SnO_2 thin films with an applied external bias [218]. Positive biasing results in quenching of the PL and improved photocurrent responses in functional solar cells. For negatively biased films, the low photocurrent may be due to either enhanced charge recombination following electron injection or decreased electron injection yields. The former would likely result in little change in the excited-state lifetime as the film is biased negative. In contrast, they observed longer excited-state lifetimes at negative bias, leading them to conclude that the applied bias controls the electron injection yield. The electron injection rate constant was estimated from a comparison of the emission decay rates for $^*\text{Ru(bpy)}_2(\text{dcb})^{2+}$ on SiO_2 (no injection) and SnO_2 at an applied potential of 0.6 V vs. Ag/AgCl , yielding 4.25×10^8 and $1.7 \times 10^7 \text{ s}^{-1}$ based on a biexponential fit. Transient absorbance measurements were used to estimate the yield of excited-state and oxidized complex. Based on the yield of oxidized sensitizer, with some assumptions, the electron injection rate increased with positive applied potential from -0.6 to 0.4 V vs. Ag/AgCl , reaching a plateau value of $4 \times 10^8 \text{ s}^{-1}$. The rate constant obtained from transient absorbance measurements, the fast component of the time-resolved photoluminescence experiments and previously reported transient microwave conductivity measurements were all in agreement.

It is surprising that Kamat, O'Regan and co-workers found a decreased injection yield at potentials near the flat-band condition. In the standard Gerischer model for sensitized planar electrodes, the low photocurrent near the flat band results because the injected carriers rapidly recombine with the oxidized sensitizer owing to the lack of a substantial depletion layer. Gerischer theory would not predict a decreased injection yield near the flat band, but this behavior can clearly be realized at sensitized nanocrystalline semiconductor films.

Durrant and co-workers reported time-resolved absorption studies of *cis*- $\text{Ru(dcb)}_2(\text{NCS})_2$ - TiO_2 at negative applied potentials [202]. In contrast to the previous studies, they did not report a change in injection quantum yield at negative potentials when compared with open-circuit or positive applied potentials. A significant increase in the charge recombination rate was observed when the semiconductor film was electrochemically reduced. Since light produces one injected electron and one oxidized sensitizer charge, recombination should formally follow a second-order equal concentration kinetic model, i.e. $[\text{Ru}^{3+}][\text{TiO}_2(\text{e}^-)]$. By electrochemically generating $\text{TiO}_2(\text{e}^-)$ the recombination rate increased substantially as expected.

2.3 Conclusions

Dye sensitization of electrodes is an old area of science with a rich history. The field has experienced renewed interest owing to the development of high surface area colloidal semiconductor electrodes. These materials yield impressive solar conversion efficiencies when employed in regenerative solar cells that have already found niche applications and have the real possibility of replacing traditional solid-state photovoltaics. Thus for the first time in history a solar cell designed to operate on a molecular level is useful from a practical point of view. It is also likely that other applications in the growing areas of molecular photonic materials will arise.

The long effective pathlength and high surface area afforded by these colloidal semiconductor materials allow spectroscopic characterization of interfacial electron transfer in molecular detail that was not previously possible. It is likely that within the next decade photoinduced interfacial electron transfer will be understood in the same detail now found only in homogeneous fluid solution. In many cases the sensitization mechanisms and theory developed for planar electrodes⁴ are not applicable to the sensitized nanocrystalline films. Therefore, new models are necessary to describe the fascinating optical and electronic behavior of these materials. One such behavior is the recent identification of ultra-fast 'hot' injection from molecular excited states. Furthermore, with these sensitized electrodes it is possible to probe ultra-fast processes using simple steady-state photocurrent action spectrum.

Figure 33 shows a Gerischer-like diagram which summarizes the kinetic processes that can be initiated with light excitation of a dye-sensitized nanocrystalline anatase

Figure 33. Gerischer-like diagram that summarizes the kinetic rate constants measured experimentally upon light excitation of a dye sensitized nanocrystalline TiO₂ (anatase) film.

film [119]. Injection from hot vibrational excited states occurs under some conditions, but injection from thermally equilibrated excited states (thexi) also has precedence. For some sensitizers, vibrational relaxation competes kinetically with electron injection and for other sensitizers injection from thexi states also occurs. Once injected, the electrons diffuse through the colloidal films on a slow millisecond to second time-scale. Carrier transport appears to involve the thermally activated hopping of electrons between trap sites. In the absence of iodide, charge recombination typically requires milliseconds for completion.

Details of this diagram, such as the nature of the redox-active states in the semiconductor, remain unknown. These and other important issues represent formidable challenges for experimentalists and theorists studying these and future generations of dye-sensitized electrodes.

3 Electron-transfer Processes in Zeolites and Related Microheterogeneous Media

Anand S. Vaidyalingam, Michael A. Coutant and Prabir K. Dutta

3.1 Introduction

The focus of this chapter is on electron-transfer processes occurring in porous media, with particular emphasis on zeolitic, mesoporous materials and sol-gel-derived materials. The definition of different classes of porous solids as specified by IUPAC is based on the pore diameter:

- microporous, if diameter < 2 nm;
- mesoporous, if diameter between 2 and 50 nm;
- macroporous, if diameter > 50 nm.

Zeolites are microporous materials with well-defined pores and crystalline frameworks. Sol-gel materials can have both micro- and mesopores, but both the framework and the pores are not well defined. Mesoporous materials have well-defined pores, but their framework structures are amorphous. These differences in structure and porosity are well reflected, as we discuss below, in the electron transfer reactions studied within these hosts. The link between these materials is the progressive increase in size of the molecules that can be encapsulated in the pores that undergo electron-transfer reactions, ranging in size from 1 nm in zeolites to enzymes of varying sizes in sol-gels. Another route to generate porosity is via pillaring of layered materials. The pillars push the layers apart and such a strategy to introduce porosity has been extensively studied with clays (smectites), layered double hydroxides, metal phosphates, etc., and forms the subject matter of a separate chapter.

As will be evident from this chapter, there is a significant body of work on electron-transfer (ET) reactions in porous materials driven by both fundamental research interests and applications in diverse areas such as sensors, catalysis and photochemical energy storage. Porous materials offer unique opportunities for ET reactions for several reasons. Porosity at the level of molecular size allows for novel spatial arrangements of molecules. Steric and electrostatic constraints can alter

chemical reactivity in ways that are impossible in a homogeneous medium. In some cases, the framework atoms can themselves play a role in the ET process. The freedom of adjusting the size of the pores to fit appropriately molecules of different shapes and sizes has made it possible to examine ET reactions involving a large number of ions and molecules.

We have restricted our discussion in this chapter to specific types of ET reactions. These include redox reactions with particular emphasis on oxidation chemistry because of the commercial importance of these reactions. In addition, photochemically induced ET reactions are extensively discussed. Numerous studies of electrochemistry with porous hosts have been reported, and there is considerable potential for the development of novel electrochemical sensors, which is discussed at length. This chapter is organized on the basis of the porosity of the materials that are discussed. The following section (Section 3.2) begins with a description of porosity in microporous, mesoporous and sol-gel materials and the synthesis routes for obtaining such porosities and assembly of molecules in these pores. ET reactions form the focus of the third section (Section 3.3). In the case of zeolites and microporous materials, redox and photoredox chemistry are treated separately (sub-sections in Section 3.3.1) since a large body of work exists in each of these areas. Electrochemical reactions involving zeolite-modified electrodes form a separate sub-section (in Section 3.3.1). For the mesoporous materials, the focus is primarily on redox reactions involving framework atoms and entrapped species (Section 3.3.2) whereas with the sol-gel materials, the photoredox chemistry of entrapped species and electrochemistry, especially the use of enzyme mediators, form the major focus of discussion (Section 3.3.3).

3.2 Description of Porous Media

3.2.1 Microporous Materials and Zeolites

Microporous materials include a large group of crystalline solids of varying chemical composition and porosity. These materials are characterized by channels and cavities of molecular dimensions. The framework structure is made up of interconnecting T–O–T' bonds, where T and T' can be Si, Al, P, Ga, Fe, Ti, Co, Zn, B and a host of other elements [1]. Materials with Si–O–Al bonding in the framework are called zeolites and are used extensively in many applications, including separations and catalysis [2]. The presence of Al in the zeolite framework leads to a charged framework and ion-exchange capabilities. In cases where the ion-exchange sites are occupied by hydrogen ions, the zeolites show remarkably strong superacid-type behavior [3]. Figure 1 shows the framework structures of some of the most extensively studied zeolites. Table 1 lists characteristic features of some zeolites, including their void volumes and the kinetic diameter of molecules that can enter the porous structure. Most of the work described in this chapter will be focused on zeolites shown in Figure 1, and the size limitation of the molecules that can be en-

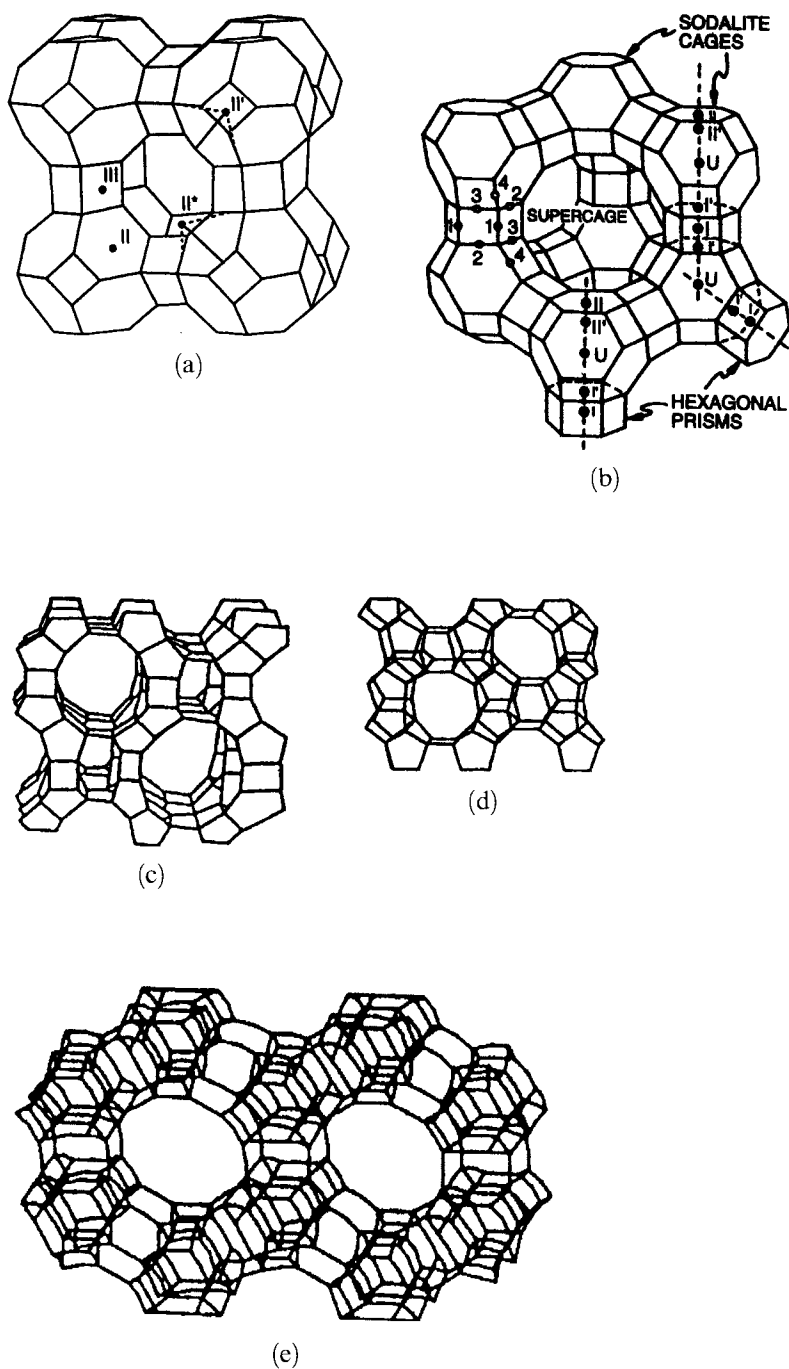

Figure 1. Framework structures of the most commonly studied zeolitic structures: (a) zeolite A; (b) zeolite X/Y; (c) mordenite; (d) ZSM-5; (e) zeolite L.

Table 1. Physical and chemical properties of some commercially important zeolites.

Type	Unit-cell compound (typical, fully hydrated)	Pore structure	Typical Si/Al ratio	Void volume/ cm ³ cm ⁻³	Kinetic diameter/ nm
A	Na ₁₂ [(AlO ₂) ₁₂ (SiO ₂) ₁₂] · 27H ₂ O	3D, 4.1 Å	1.0	0.47	0.39
X	Na ₈₆ [(AlO ₂) ₈₆ (SiO ₂) ₁₀₆] · 264H ₂ O	3D, 7.4 Å	1.0–1.5	0.50	0.81
Y	Na ₅₆ [(AlO ₂) ₅₆ (SiO ₂) ₁₃₆] · 250H ₂ O	3D, 7.4 Å	>1.5–3	0.48	0.81
L	K ₉ [(AlO ₂) ₉ (SiO ₂) ₂₇] · 22H ₂ O	1D, 7.1 Å	2.6–3.5	0.32	0.81
Mordenite	Na ₈ [(AlO ₂) ₈ (SiO ₂) ₄₀] · 24H ₂ O	1D, 6.5 × 7.0 Å	4.7–5	0.28	0.63
ZSM-5	(TPA, Na)[(AlO ₂)(SiO ₂) ₃₀] · 10H ₂ O	3D, 5.4 × 5.6 Å 5.1 × 5.5 Å	10 100	0.34	0.60

capsulated is of the order of 13 Å in zeolites X/Y (12-ring pores). Microporous frameworks with larger pores have only recently been synthesized, including aluminophosphate VPI-5 (18-ring pores, 13 Å channel), gallophosphate cloverite (20-ring pores, 13 Å window and 30 Å cavities) and aluminosilicate UTD-1 (14-ring pores, 10 Å channels) [4]. It is expected that reports of ET reactions in these hosts will be forthcoming.

Microporous materials are typically synthesized by a hydrothermal process, which involves mixing appropriate reactants in an aqueous medium followed by heat treatment [5]. Even though the process is relatively simple, the development and control of porosity, which determines the ultimate practical use of these materials, is not easy to predict. This is primarily because crystal growth of these materials is a very complicated chemical process [6]. For example, in zeolite formation, the silicon- and aluminum-containing reactants dissolve in the presence of base to produce many soluble species [7]. Speciation is strongly influenced by the pH, temperature, cations and structure-directing agents [8]. Insoluble aluminosilicates (commonly referred to as gel) are rapidly formed by reaction of the solubilized species. Thus, this system is typically in a state of supersaturation for many of the aluminosilicate species. After an induction period that can extend from hours to weeks, nuclei are formed. The nuclei grow using nutrients from the solution or the dissolving gel to form crystals. Figure 2 shows a schematic description of the crystallization process of microporous materials [9]. The complexity of the process is evident from the numerous chemical processes that occur during crystallization.

Typically, the interesting open porous structures are intermediates in the synthesis process and with longer crystallization times, condensed structures will form. Because kinetic stabilization is necessary for the formation of open pore structures, profound effects are manifested by changing the synthesis conditions. The interplay between the inorganic reactants and organic additives also influences the crystal growth process. Hence zeolite synthesis is an exciting area of research, with major discoveries of frameworks being reported on a regular basis. However, the critical

Figure 2. Schematic representation of the crystallization process of microporous materials.

discoveries of new frameworks usually occur by trial and error. Spectroscopic probes that have found considerable use in the past decade include NMR spectroscopy [10, 11] and Raman spectroscopy [12]. Other techniques that have provided information on the early stages of zeolite nucleation include small- and wide-angle X-ray and neutron scattering [13].

Assembling molecules within zeolites

The microporosity of zeolites and other microporous materials makes it very convenient to introduce molecules into the structure. Several strategies exist, depending on the size and nature of the species. Positively charged species can be ion exchanged into the zeolite from aqueous solution, provided that they are small enough to penetrate through the ring openings. Many inorganic and organometallic complexes, such as $[\text{Ru}(\text{NH}_3)_6]^{3+}$, $[\text{Co}(\text{NH}_3)_4]^{2+}$ and $[\text{Co}(\text{C}_5\text{H}_5)_2]^+$, as well as organic cations such as viologens can be readily exchanged into the zeolite [14]. The loading levels can be controlled by adjusting the concentration of the molecule in the ion-exchanging solution. For neutral molecules, the molecule can either be transported via the vapor phase into the empty space of the dehydrated zeolite, or introduced via a solvent into the dehydrated zeolite. Examples include the introduction of benzene into zeolite Y via vapor phase and the introduction of pyrene into zeolite Y using cyclohexane as solvent [15]. Metal carbonyl complexes of iron, ruthenium and molybdenum have also been introduced via the vapor phase [16].

A third approach is the construction of molecules inside the zeolite itself. Such a strategy has been particularly successful with the faujasitic zeolites, because of the possibility of synthesizing molecules within the supercage that are large enough that they cannot be introduced directly through the window openings. This procedure has been referred to as 'building a ship in a bottle' synthesis and typically incorpo-

Figure 3. $\text{Ru}(\text{bpy})_3^{2+}$ entrapped inside a zeolite Y supercage synthesized by the ship-in-a-bottle approach.

rates steps to obtain the necessary building blocks into the supercage, followed by appropriate treatment to synthesize the desired complex. A good example is the synthesis of $[\text{Ru}(\text{bpy})_3]^{2+}$ in zeolite Y. This molecule has a dimension of 12 Å, and cannot be introduced through the 12-membered ring openings, as is obvious from Figure 3. The following scheme has been adapted from the pioneering work of Lunsford and co-workers [17]:

Under careful anaerobic conditions, $[\text{Ru}(\text{NH}_3)_6]^{2+}$ can also be used as the starting material, avoiding the formation of acidic compounds during the synthesis process. This is of particular importance in assembling complexes in low Si–Al zeolites such as zeolite X [18]. Recently, Kincaid and co-workers synthesized ruthenium polypyridyl complexes with mixed ligands in zeolite Y [19]. Intrazeolitic entrapped complexes $[\text{Ru}(\text{L})_n(\text{L}')_{3-n}]^{2+}$ where $\text{L}, \text{L}' = 2,2'$ -bipyridine, 2,2'-bipyrazine and 4-methyl- and 4,4'-dimethyl-2,2'-bipyridine have been synthesized. The strategy has been first to synthesize the bis-complex $[\text{Ru}(\text{L})_2(\text{H}_2\text{O})_2]^{2+}$ in the zeolite followed by insertion of a third ligand. This strategy opens up many more possibilities for the synthesis of new complexes. Phthalocyanine, Schiff base (salen) and tetraethylenediamine (tetren) complexes are examples of other ligands used for complex formation in zeolite Y [20]. Structures of several complexes and ligands used in zeolite Y are shown in Figure 4.

Another approach developed by Balkus and co-workers involves the use of organometallic complexes such as phthalocyanines and cobalticinium cations as tem-

Figure 4. Structures of several ligands complexes synthesized in zeolite Y by the ship-in-a-bottle strategy: (a) tetren; (b) pyren; (c) Co(salen); (d) Fe(phthalocyanine); (e) [Ru(bpy)₂daf]²⁺; (f) [Ru(bpy)₃]²⁺; (g) [Ru(bpz)₃]²⁺. *N,N'*-Ethylenebis(salicylideneiminato) (2-) ion = salen, tetraethylenepentamine = tetren, 2,2'-bipyridine = bpy, 4,5-diazafluorene = daf, 2,2'-bipyrazine = bpz.

plates for the formation of microporous materials, thereby ensuring entrapment in micropores during the framework synthesis [21]. It is clear that our sophistication in synthesizing molecules within zeolite cages is continually being enhanced, with the ultimate goal being to develop chemistry parallel to that of conventional synthesis. The advantage of these synthetic advances in electron-transfer chemistry will become obvious as we proceed.

Environment within the zeolite structure

One of the important differences between molecules in zeolite cages and species isolated in other matrices such as cyclodextrins [22], micelles [23], vesicles [24] and polymers [25] arises from the fact that the zeolite can be an active host and influence the structure and reactivity of the encapsulated molecules. The nature of the intra-zeolitic environment has been extensively studied and the influence of polarity, steric and electrostatic effects on encapsulated molecules is beginning to be well understood.

Micropolarity

Optical spectroscopy of several polyaromatic hydrocarbon probes has provided information about the polarity of the intrazeolitic environment. The change in intensities of the two vibronic components (380 versus 370 nm) of the fluorescence of pyrene has been used for the estimation of micropolarity in micelles, cyclodextrins and other media [26]. This methodology has also been applied to zeolites [27]. Solvatochromic effects have also been exploited to obtain information about zeolite as a 'solvent' [28]. Using salicylidene as a probe and based on changes in its electronic and Raman spectra, it was concluded that Na⁺-exchanged zeolite Y behaved primarily like a solvent with α character, indicative of its ability to undergo hydrogen bonding. Polarity within faujasitic zeolites has recently been measured with the probe molecules Nile Red, pyrene-1-carboxyaldehyde and coumarin 500 [29]. The effect on the intrazeolitic polarity by the framework cations was negated by the presence of water or polar solvents. In the absence of solvent, the polarity was found to be controlled by the charge of the cation, and in all cases the zeolites were found to be more polar than water. This 'superpolarity' led to switching of the $n\pi^*$ and $\pi\pi^*$ states of acetophenones, an effect that is not found even in the most polar organic solvents [29].

Zeolite rigidity

The zeolite framework is relatively rigid under ambient conditions; however, at higher temperatures, there appears to be increased flexibility and typically excluded molecules can penetrate into the system [30]. For example, 1,3,5-triisopropylbenzene with a diameter of 9.3 Å will diffuse into zeolite X supercages at temperatures of 450–500 K. The rigidity of the framework is manifested most vividly if the entrapped molecule fits very tightly into the intrazeolitic space. Sodalite cages are the building blocks of zeolite X, Y and zeolite A (Figure 1a and b). The internal

diameter of these cages is 6.6 Å, and can accommodate the tetramethylammonium (TMA) cation, which is of the same size as the cage. Indeed, for TMA⁺ entrapped in sodalite cages, this fit was tight enough that the C–N symmetric stretching vibration of the TMA⁺ cation was shifted from 752 to 761 cm^{−1} upon encapsulation [31], comparable to what is observed for tetraalkylammonium salts under high pressures.

Kincaid and co-workers have exploited the steric effect in altering the excited-state photophysical properties of [Ru(bpy)₂(daf)]²⁺, where daf = 4,5 diazafluorene [32]. Aqueous solutions of this complex exhibit very weak luminescence, with lifetimes shorter than 10 ns at room temperature. Upon encapsulating this molecule into zeolite Y supercages, the fluorescence intensity increases by a factor of 100 and the excited-state lifetime is increased to 302 ns.

Similar dimensions of an entrapped molecule and the intrazeolitic volume can lead to novel structural perturbations. This is exemplified by the singlet excited lifetime of *trans,trans*-1,4-diphenylbutadiene [33]. In faujasitic zeolites, the lifetime is of the order of 0.6 ns, comparable to that in solution. However, upon incorporation into the channel crossings of ZSM-5, the lifetime increased to 12.7 ns, since the rotation around the π -bond is no longer possible. Entrapment of a molecule inside a zeolite cage can restrict access to it by other molecules. Reactive species can be trapped indefinitely, as is observed for cation radicals formed by the adsorption of α,ω -diphenylpolyenes (e.g. *trans*-stilbene, diphenylbutadiene, diphenylhexatriene) into Na–ZSM-5 [34]. These cation radicals are unstable in solution (lifetime of microseconds) or other solid matrices (lifetime of seconds), but are readily stabilized indefinitely in ZSM-5. This stability arises because the double bond is protected from external reagents by the phenyl rings that extend into the channels. We shall discuss how stabilization via entrapment of tropylium ion and Ru(bpy)₃³⁺ in zeolite Y gives rise to novel ET chemistry in Section 3.3.1.

Electrostatic effects

In the hydrated form of the zeolite, the intracrystalline space is filled with water molecules. However, upon dehydration, without the mediating effects of the high dielectric constant of water, the effects of the negatively charged aluminosilicate framework become apparent. In the early days of zeolite chemistry, it was calculated that electric fields could reach up to 6.3 V Å^{−1} at distances of a few ångströms from a cation site (S II in zeolite Y, Figure 1b) [35]. Fields of this magnitude can readily polarize absorbed molecules at close proximity to these sites, thereby altering the reactivity. Studies of the infrared spectra of adsorbed molecules such as CH₄ and N₂ in zeolite A show the evidence of Stark field splitting, and fields of the order of 1 V Å^{−1} were estimated [36]. How rapidly these fields fall off from the framework toward the center of the cage still needs to be determined. Calculations of electrostatic fields from X-ray diffraction data promises to be a good method for obtaining this information [37]. We shall discuss later how intrazeolitic electrostatic fields have been exploited for promoting ET reactions and hydrocarbon oxidation.

Figure 5. (a) SEM of nanocrystalline zeolite Y (bar = 100 nm). (b) Transmission electronic spectrum of a dispersion of $\text{Ru}(\text{bpy})_3^{2+}$ entrapped in nanocrystalline zeolite Y.

Nanocrystals and membrane forms of zeolites

Zeolites, as synthesized, are typically formed as powders. Most experimentation is done with the powder form, as such or in the form of pressed pellets. Two forms of zeolites that are of considerable interest for ET reactions are nanocrystals [38] and membranes [39]. In the case of nanocrystals, the dispersion in a solvent can be almost optically clear, which makes it possible to apply transmission optical spectroscopic studies to follow reactions occurring within the cages. Figure 5a shows a scanning electron micrograph (SEM) of nanocrystalline zeolite Y and Figure 5b shows the absorption spectrum of $\text{Ru}(\text{bpy})_3^{2+}$ –nanocrystalline zeolite Y obtained in the transmission mode [40]. Zeolites have also been embedded into poly(dimethylsiloxane) (PDMS) polymers to make transparent films [39]. Figure 6b shows the absorption spectrum (transmission mode) of the chromophore TMT^+ (Figure 6a) entrapped in zeolite Y and made into a PDMS film. The extinction coefficient of the dye in the zeolite is comparable to that in solution, indicating minimal perturbation by the zeolite framework. Transient species in zeolites can also be characterized via incorporation into films. It is also expected that quantitative parameters such as quantum yields will be more easily obtained with these forms of ‘transparent’ zeolites rather than powders. Another advance in this field is the development of self-standing zeolitic films [41]. Figure 7 shows the SEM pictures of top and side view of a chabazite film, which can be prepared readily with dimensions of centimeters [42].

Figure 6. (a) Structure of TMT⁺. (b) Transmission optical spectrum of zeolite-entrapped TMT⁺–polymer film.

In summary, it is clear that the zeolite is a novel host for the entrapment of molecules and the rigidity and the charged nature of the framework allow for steric and electrostatic effects on the encapsulated molecules. Isolation of entrapped molecules can also influence their reactivity. The interest in zeolites as hosts for electron-transfer reactions stems from a combination of properties, including

- high surface area and adsorption capacity;
- redox-active framework elements;
- size of channels and cavities of molecular dimensions (5–13 Å);
- possibility of entrapment of molecules;
- electrostatic effects and unique solvation manifested in the intrazeolitic medium;
- formation of nanocrystals and films.

3.2.2 Mesoporous Materials

As discussed above, zeolites and other microporous materials have channels and cages of 5–13 Å, which is typical of the size of many molecules of interest. Mesoporous materials serve to extend the range of porosities, with well-defined and controllable pores increasing readily from 15 Å. Research in the field of mesoporous materials began in earnest in 1992 with the discovery of the M41S class of materials by researchers at Mobil Research and Development Corporation [43]. Thus, of all the porous materials being discussed in this chapter, it is the most recent. However, the possibility of the precise tuning of pore sizes in a range that was previously

unattainable has generated intense excitement and large numbers of publications, including several review articles demonstrating the use of these materials as novel hosts, have appeared [44]. In this section, we provide a brief description of mesoporous materials and their synthesis and discuss ET reactions using these hosts in Section 3.3.2.

Mesoporous materials are defined as inorganic materials with pores with diameters in the range 20–500 Å and include sol–gel-derived aerogels, pillared layered structures and the M41S class materials. Since the sol–gel-derived materials have pore structures of varying dimensions, and have also been extensively studied, we shall discuss these materials separately. It is important to mention that the M41S class and the layered materials have a considerably better defined pore structure than the aerogels. The crystallinity in the M41S class arises from the long-range ordering of the pore structure rather than crystallinity of the framework, the latter being the case for zeolites.

The porosity in the M41S family of materials is typically generated with the use of surfactants as structure-directing agents. Most work has been done on the synthesis of silicate-based frameworks although, as we discuss later, other elements can also be incorporated into the framework (such as Al, V and Ti) and nonsilicon-containing frameworks can also be made (such as Ti and Zr). The first synthesis reports involved compositions including a silica source (tetraethylorthosilicate, Ludox®, fumed silica, sodium silicate), a cationic surfactant such as cetyltrimethylammonium bromide, a base (sodium hydroxide) and water. Upon heating these reactants to temperatures $>100^{\circ}\text{C}$ for several days, a solid crystalline material is obtained. Upon burning off the surfactant, the mesoporous material is obtained. Figure 8 shows a TEM picture of MCM-41, where the pores are arranged in a hexagonal geometry [43a]. Figure 9 shows the scheme proposed in the original publication detailing the synthesis of MCM-41 [43]. This mechanism, which was dubbed the ‘liquid crystal templating’ mechanism, suggests that the surfactant forms a liquid crystal phase and the silicate anions interact with the positively charged head groups and orient and condense to form the inorganic framework. The calcination step leaves the inorganic shell, which has the same structure as that

Figure 8. TEM of MCM-41 (text box corresponds to 300 Å).

Figure 9. Schematic representation of formation of MCM-41 by a liquid crystal templating mechanism: (1) liquid crystal phase initiated and (2) silicate anion initiated.

of the hexagonal array of the surfactant. The pathway marked (2) in Figure 9 involves association of silicate ions with the micellar rods and self-assembly into the organized MCM-41 structure. A number of studies have since appeared focusing on the mechanism of formation of the MCM-type materials [44b] and, although the definitive chapter on this has not been written, it is agreed that the pathway (1) shown in Figure 9 is only possible if the surfactant concentration exceeds critical micelle concentration (CMC) so that liquid crystal phases exist in the medium [45]. Under most synthesis conditions [46], this is not the case and a more generalized version of the growth process begins with the interaction between the silicate species and the surfactant. These interactions may lead to the formation of an initial liquid crystalline [47] or a lamellar phase [48]. Figure 10 is a representation of a self-assembly process [49] that begins with specific interactions between silicate ions (such as $[\text{Si}_8\text{O}_{20}]^{8-}$ [50]) present at high pH and the surfactants to produce a silicatropic liquid crystal phase, followed by condensation of the silicate anions to form the inorganic framework.

It appears that the matching of the charge density of the surfactant with the ionic species is the important step in the assembly process [44b]. Thus, for example, a cationic surfactant S^+ can direct the formation of negatively charged inorganic species (I^-) through a direct $\text{S}^+ \text{I}^-$ interaction (e.g. MCM-41) or positively charged inorganic species I^+ through the mediation of an anion X^- as in $\text{S}^+ \text{X}^- \text{I}^+$ (e.g. silica, $\text{pH} < 2$).

Other types of interactions that can also lead to mesoporous silicas involve hydrogen bonding interactions of the structure-directing agent, such as an alkylamine or polyethylene oxide with neutral silicon containing species, such as hydrolyzed $\text{Si}(\text{OR})_4$ via an S^0I^0 route [51]. Mesoporous materials formed via these routes do not have the long-range order as in the M41S materials, but appear to have thicker framework walls, leading to enhanced thermal stability and worm-like pores. Also, the surfactant, since it is not ionically bound, can be extracted with solvents. In addition to the hexagonal MCM-41, cubic (MCM-48, SBA-1) and lamellar (MCM-50) structures have also been reported [52].

Another route to mesoporous materials is via intercalation of surfactants into layered silicates, such as kanemite. The flexible silicate sheets expand and cross-link

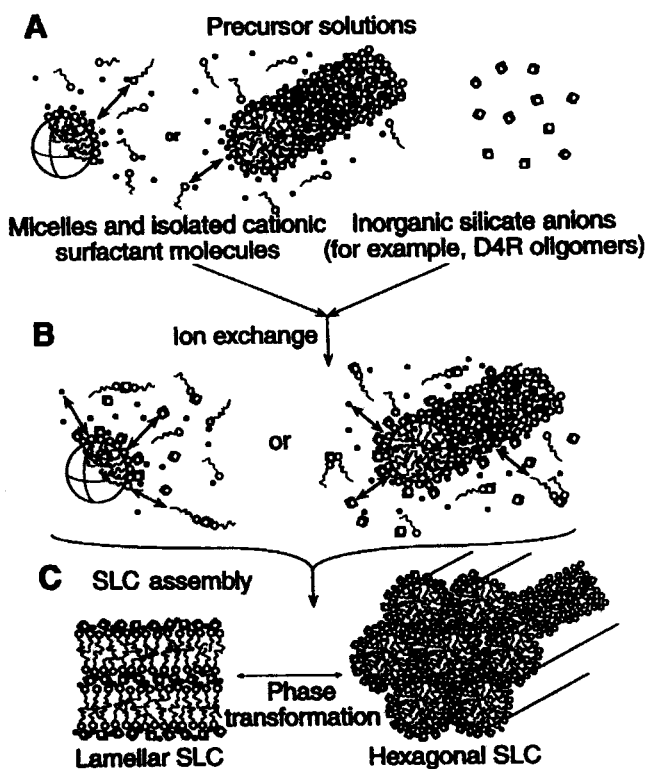

Figure 10. An electrostatic self-assembly process for forming mesoporous materials. (A) Organic and inorganic precursor solutions. with each other to develop the porosity [53]. These materials (abbreviated as the FSM family) tend to be more thermally stable than the MCM-type materials.

A considerable amount of research has also been done on incorporating other metal atoms into the mesoporous silicas. Establishing ion-exchange capability and acidity of mesoporous materials opens up many potential applications. This has primarily been done by insertion of tetrahedral Al into the framework. The level of substitution of silicon by tetrahedral Al depends on the reactants and method of preparation, with the highest amounts being in the region of 9 mol % [54]. Higher levels of Al could be inserted (up to 50 mol %), by using cube-like aluminosilicate species, but these materials will dealuminate, with conversion of the tetrahedral to octahedral Al [55]. Other metals that have been introduced into the framework include Ti, V, Cr, Mn, Fe, Mo, Zr and Nb, and some of these are relevant in ET reactions. Typical levels of these metals are in the range 1–2 mol %, although some exceptions, such as 17 mol % Zr insertion, have been reported [44b]. Several spectroscopic studies have confirmed that insertion of the metal into the framework occurs, rather than the formation of metal oxides. With Cr^{3+} , however, only small amounts will substitute into the framework, as is also observed with zeolites [56].

Typically, the synthesis conditions described above lead to the formation of mesoporous powders, with crystallite sizes of the order of microns. However, for

many applications, thin films of these materials would be of interest. Early attempts led to films where the pore channels were parallel to the substrate surface [57]. However, for practical applications, it would be necessary to have the pore channels perpendicular to the substrate in order to make them accessible to molecules. Use of external forces such as flow of reactants as well as strong magnetic fields have been shown to provide ordering of pores [58]. By manipulating the surfactant concentration at levels past the CMC, hexagonal as well as mixed cubic and hexagonal films with accessible pore channels have been made [59].

Nonsilicate compositions using the surfactant templating route did not result in making mesoporous materials, especially after surfactant removal. Alternative routes using metal alkoxides in the presence of a chelating agent, such as acetylacetone, yielded the first mesoporous titanium dioxide with a narrow pore size distribution and a surface area of $200 \text{ m}^2 \text{ g}^{-1}$ [60a]. Mesoporous niobium, tantalum and zirconium oxides have been reported [60b–d]. Of particular interest is mesoporous manganese oxide, with crystalline framework walls and semiconducting properties [61]. Mesoporous aluminas with surface areas as high as $400\text{--}710 \text{ m}^2 \text{ g}^{-1}$ have also been synthesized [62].

The larger pores of mesoporous materials have extended ET reactions to larger molecules than those studied in zeolites, but the amorphous nature of the framework and the presence of silanol groups along the pores have had other interesting consequences and are discussed later.

3.2.3 Sol–Gel Materials

Sol–gel processing is used to synthesize mainly inorganic materials starting from suitable monomers by a polycondensation process, and is an area of considerable research interest [63]. Various stages can be recognized in this process, including the formation of a colloidal suspension (sol) which via gelation leads to a solid phase (gel). Drying of the gel forms a xerogel (dry gel), which upon heating will transform into a denser and in some cases, a crystalline material. Almost all inorganic oxides, and also many mixed oxides, have been made by the sol–gel method, including SiO_2 , TiO_2 , ZrO_2 and Al_2O_3 .

The most extensive studies in this field have focused on SiO_2 and are reflected in this chapter. Typically, sol–gel materials are produced via controlled hydrolysis of alkoxides, as shown with silicon:

SiO_2 is a simplified representation of the final product, a more appropriate representation being $(\text{SiO}_m\text{H}_n)_p$ because of the presence of silanol groups and adsorbed water. The resulting materials can be highly porous, with pores typically in the range of tens of ångströms and surface areas that can reach hundreds of $\text{m}^2 \text{ g}^{-1}$.

The great interest in sol–gel chemistry arises not only because of the simplicity of the procedure required to generate the material and the ease of doping, but also for several technological reasons. It is straightforward to obtain a sol–gel material in a particular shape, be it in the form of powders, monoliths, thick/thin films or fibers.

The synthesis technology easily lends itself to miniaturization. Sol–gel processing can be adapted to ink-jet technology. The silica-like matrix which has been the most investigated is chemically, photochemically, electrochemically and thermally inert.

ET processes occurring inside the porous structure of sol–gel materials require entrapment of molecules in sol–gel matrices. Two basic strategies have been reported in the literature. Philipp and Schmidt, in a pioneering study, exploited the hydrolytic stability of Si–C bonds to prepare sol–gel materials with covalently held organic and organometallic groups [64]. Avnir and co-workers pioneered an alternative route to entrapment by carrying out sol–gel polymerization in the presence of a host molecule [65]. The advantage of the covalently bonded organic–inorganic system is the irreversibility of the bond, resulting in permanent entrapment. The doping procedure, on the other hand, is simpler and most molecules can be trapped in this fashion.

Nature of the porous structure

Considering that the focus of the chapter is to examine ET processes in the pores of sol–gel material, it is useful to summarize the nature of the porous structure. The chemical reactions involved in forming the oxide involve hydrolysis of the Si–OR group and the condensation of the Si–OH and Si–OR groups to form an Si–O–Si framework. Varying the synthesis conditions influences the different hydrolysis and condensation reactions and thereby allows for control of the porous property of the sol–gel-derived materials. Silica gels made under acidic conditions tend to exhibit microporosity, whereas processing under basic conditions leads to mesoporosity [66]. It has been proposed that in sol–gel oxides the porosity is controlled by both the nature of the internal structure of the primary particles and by how the particles aggregate [63g]. Acidic conditions tend to lead to smaller primary particles and hence microporosity, whereas basic conditions give larger particles, giving rise to mesoporosity. Figure 11 shows a transmission electron micrograph (TEM) of a xerogel derived from $\text{Si}(\text{OCH}_3)_4$, demonstrating the physical nature of the porosity [63g].

Considerable research has been done on optical properties of molecules entrapped in xerogels, providing information on porosity. With Rhodamine 6G as a probe, it was concluded that the matrix does an efficient job of isolating molecules in a reasonably polar environment due to nests of hydroxyl groups [65]. Because of the isolation of molecules from each other, materials with high extinction coefficients can be prepared by loading the sol–gel with dyes, although a limit to this process has been noted for $\text{Ru}(\text{bpy})_3^{2+}$ and proteins [67, 68]. The vibronic structure of the fluorescence spectrum of pyrene and excimer formation of pyrene have been used to monitor the generation of pore structure and it was found that the pyrenes ended up isolated in microporous cages [69].

Homogeneity of the pores was noted based on single excited-state lifetimes obtained for probes such as $\text{Ru}(\text{bpy})_3^{2+}$ on $\text{SiO}_2\text{--TiO}_2$ [70] and biphenylcarboxylic acid on SiO_2 [71]. The lifetime of $\text{Ru}(\text{bpy})_3^{2+}$ was found to increase from 0.6 μs in solution (1×10^{-3} M) to 1.9 μs upon encapsulation. This increase in the lifetime is characteristic of tight encapsulation, as has been noted previously for encapsulation of $\text{Ru}(\text{bpy})_3^{2+}$ into cellulose acetate and proposed to arise from destabilization of the ^3dd (metal-centered) state [72].

Figure 11. TEM of an $\text{Si}(\text{OCH}_3)_4$ -derived xerogel.

Photochemical stability is also increased upon encapsulation, e.g. the degradation half-life of 4-oxazine is increased fourfold by entrapment compared with solution [70]. Based on the emission spectrum of Eu^{3+} (in particular the $^5\text{D}_0 \rightarrow ^7\text{F}_2$ band at 615 nm), it has been noted that as the solvent is removed by heating, the symmetry around the cation decreases during the gel to glass transition [73]. Figure 12 shows the emission spectra of Eu^{3+} as the sol–gel is heated from 298 to 873 K [73]. At room temperature, the low intensity is due to electron–phonon coupling with the C–H and O–H groups. As the temperature increases, solvent begins to leave the gel and Eu^{3+} forms covalent and coordinative bonds with the sol–gel framework. Both of these events result in a lowering of the symmetry around the probe, causing band broadening and an increase in intensity of the $^5\text{D}_0 \rightarrow ^7\text{F}_2$ band at 615 nm. The degree of dryness of the sol–gel material controls both the rigidity of encapsulation and access to the probe molecule. Spiroyrans will exhibit photochromism via isomerization between the colorless spiro form and the colored mercocyanine zwitterion only in wet sol–gel SiO_2 [74].

3.3 Electron-transfer Reactions

3.3.1 Microporous Materials and Zeolites

Redox chemistry

Zeolites have found extensive applications in the field of petroleum cracking as solid acid catalysts [75]. With the introduction of redox metal atoms into the framework,

Figure 12. Emission spectra of Eu(III) at various temperatures during the gel to glass transformation of a silica sol-gel.

their potential extends into the realm of ET reactions and has been the subject of several reviews [76]. Redox molecular sieves, as they are popularly known, can be prepared in three different ways: (1) framework substitution, (2) ship-in-a-bottle encapsulation of complexes and (3) ion exchange with or without the formation of cluster species.

Involvement of framework atoms

The common means of introducing redox catalytic activity in zeolites is by the substitution of framework atoms such as Si, Al or P with redox-active metal cations. This has been accomplished by two different methods: (1) hydrothermal synthesis and (2) post-synthesis modification. Irrespective of the method of preparation, with the notable exception of titanium silicalites, these redox metals in the framework are susceptible to leaching due to the solvolysis of M–O bonds [77]. Even the Ti silicalites suffer from leaching under basic conditions [76a].

Various redox metals, including Ti, V, Cr, Mn, Fe, Co, Cu, Zn, As, Zr and Sn, have been incorporated into microporous materials such as silicalites through hydrothermal synthesis by the addition of the respective cations to the synthesis gel. The disadvantages of this method include the time-consuming optimization of synthesis procedure for each metal-zeolite combination and the necessity of Al for crystallization of certain structures. The presence of Al leads to Brønsted acidity

and increased hydrophilicity resulting in unwanted acid-catalyzed side reactions and reduced selectivity, respectively [78].

Post-synthesis modification involves isomorphous substitution of framework atoms with the desired redox metals either in aqueous media with soluble metal salts or in the gas phase with volatile chlorides. Incorporation of Ti into the framework of faujasite, zeolite- β and ZSM-5 has been accomplished by treating the zeolite with ammonium titanyl oxalate, TiCl_4 or $\text{Ti}(\text{O}i\text{-Pr})_4$. Substitution of V for framework atoms has been reported with VOCl_3 vapor. A more generalized method involving the reoccupation of the silanol nests created by the deboronation of borosilicates (ZSM-5 and zeolite- β) shows considerable promise for the incorporation of redox metals into the framework [79].

Interest in framework-substituted zeolites stems from their use as catalysts in liquid-phase oxidations. The most common mechanisms for oxidations involving the framework metal atoms are (1) free radical autoxidation and (2) catalytic oxygen transfer, represented schematically in Figure 13a and b, respectively [76]. Although both mechanisms could use O_2 , the commonly employed oxidants are hydrogen peroxide and alkyl hydroperoxides such as *tert*-butyl hydroperoxide (TBHP). Non-zeolitic microporous materials such as Co aluminophosphate (AIPO) with cobalt as the redox center could involve alkoxy and alkylperoxy radicals as intermediates and hence could be categorized as homolytic free radical autoxidation (Figure 13a). The catalytic oxygen transfer mechanism is heterolytic in nature, as shown in Figure 13b. In the case of early transition metals such as Ti, this mechanism involves the formation of a peroxometal and the metal center undergoes no change in oxidation state. In the case of first-row and late transition metals, an oxometal is involved and the metal undergoes a two-electron oxidation by the oxidant followed by reduction by the substrate. The oxometal route is the major pathway for gas-phase hydrocarbon oxidation (Mars–van Krevelan mechanism), but in the liquid phase it is much less common owing to the competing free radical autoxidation pathway.

Titanium silicalites

Of the various redox metal–zeolite systems that have been studied, none parallels titanium silicalites (TS-1, TS-2) in the extent of investigation, catalytic versatility and long-term stability [80]. The only limitation of these Ti silicalites is their small pore size ($5.1 \times 5.5 \text{ \AA}$ along the $\{100\}$ channels), restricting the size of substrates and oxidants. Larger substrates show much lower reactivity and turnover numbers and bulky oxidants such as TBHP are sluggish, limiting their usefulness. This significant limitation has been overcome with the use of larger pore systems such as zeolite- β , as will be discussed later.

Alkane oxidation to alcohols, aldehydes and ketones has been extensively studied and it was found that the smaller linear alkanes show higher turnovers than the longer linear, branched and cyclic alkanes [81]. Although the turnover numbers are found to increase with the addition of methanol as a co-solvent, the general role of the co-solvent in selectivity is still not clear. Catalytic epoxidations of relatively inert alkenes such as propylene and allyl chloride were found to be facile under mild

Figure 13. (a, b) Schematic representation of the oxidation pathways using redox molecular sieves: (a) homolytic free radical autoxidation and (b) heterolytic oxygen transfer. (c) Oxidation of styrene to styrene oxide and transformation to 2-phenylacetaldehyde using a bifunctional Ti-silicalite catalyst.

conditions [82]. The presence of Brønsted acid sites could be a boon or bane depending on the substrates and the desired product. One instance where the Brønsted acidity augments the catalytic ability through bifunctional catalysis is the oxidation of styrene to styrene oxide followed by the acid-catalyzed rearrangement to form 2-phenylacetaldehyde, shown in Figure 13c [83]. Selective oxidation of alcohols results in the conversion of primary alcohols to aldehydes and secondary alcohols to ketones as major products [84]. Methanol is not very reactive and tertiary alcohols are converted slowly to the corresponding alkyl hydroperoxides. Chemoselectivity has been illustrated by the oxidation of allyl alcohol, which results primarily in epoxidation of the double bond rather than oxidation of the OH group [85].

One of the most successful industrial applications of titanium silicalites has been the hydroxylation of phenol to yield a 1:1 mixture of catechol and hydroquinone

[86]. The selectivity to catalyze ring oxidation over side-chain oxidation has been illustrated in the case of nuclear hydroxylation of toluene, anisole and *m*-cresol [87]. Catalytic conversion of NH_3 to hydroxylamine has been cleverly exploited for the ammoximation of aldehydes and ketones via the reaction of the hydroxylamine and the carbonyl compound. Ammoximation of cyclohexanone to cyclohexanone oxime, a raw material for nylon-6 production, illustrates the use of redox molecular sieve catalysts for an industrially important and commercially viable process [88]. Other applications include oxidation of primary and secondary amines to the corresponding hydroxylamines and hydroximes, respectively [89], anilines to the corresponding symmetrical azobenzenes [90], thioethers to sulfoxides and sulfones [85a] and secondary amines to nitrones in the presence of methanol [91]. Cleavage of C=N groups in oximes, tosylhydrazones and imines has also been reported [92].

Other titanium frameworks

Large pore structures with Ti in the framework that can accommodate larger substrates and oxidants include Ti-zeolite- β [93], Ti- AlPO_4 -11 [94], Ti-ZSM-48 [95], Ti- AlPO_4 -5 [94] and Ti-Si AlPO_4 [96]. The aluminum content of these catalysts is a potential problem and requires the Brønsted acidity to be neutralized by ion exchange with alkali metals. Ti-zeolite- β can epoxidize branched and cyclic alkenes with the bulky TBHP as oxidant, but the epoxide undergoes cleavage or ring opening, if Brønsted acidity is present. A good example of such a system is the catalytic oxidation of 1-octene with H_2O_2 over ion-exchanged Ti-Al-zeolite- β , giving almost exclusively octane-1,2-diol in the case of H^+ -exchanged and epoxide in the case of Li^+ -exchanged zeolite [78a]. The product selectivity, due to pore size restriction, can be demonstrated with the oxidation of linalool using TBHP giving furans and not pyrans [76a]. An example of industrially important catalysis is the ammoximation of *p*-hydroxyacetophenone in the presence of hydrogen peroxide, ammonia and methanol to the corresponding oxime, a crucial intermediate in the synthesis of the analgesic paracetamol [97]. Cyclohexanone ammoximation with Ti-zeolite- β is not useful, as the oxime can undergo a Brønsted acid catalyzed, Beckmann rearrangement to form caprolactam, which polymerizes to nylon-6, blocking the pores [97]. Ti-zeolite- β can also catalyze phenol hydroxylation, alkane oxidation and conversion of anilines to symmetrical azobenzenes [76a]. Ti-Si AlPO_4 has been used for the oxidation of cyclohexene and the product selectivity has been reported to be dependent on the oxidant, the main product being the 1,2-diol with H_2O_2 and epoxide with TBHP [96]. Ti- AlPO_4 has also been reported to catalyze phenol hydroxylation [94].

Other redox microstructures

Redox silicalites with elements other than titanium have found catalytic applications in various organic oxidations. V-ZSM-11 is reported to catalyze alkane oxidation and is found to oxidize even primary C-H bonds [98]. Detailed studies indicate that V silicalites are better than Ti silicalites for alkane oxidation, as it is found that molecular oxygen can act as the oxidant in the former case [99]. V-ZSM-5 shows selectivity toward alcohol oxidation in allyl and methallyl alcohols

with hydrogen peroxide [85a]. Cr-ZSM-11 catalyzes the cleavage of the double bond in methyl acrylate to give methyl glyoxalate and is also capable of selective epoxidation of geraniol [100]. Silicalites with various structures and metals such as V-ZSM-12 [101], V-EU-1, V-THETA-1 [102], As-ZSM-5 [103] and Sn-ZSM-11 [104] are reported to catalyze phenol hydroxylation and V-ZSM-11, V-ZSM-5 [105], Sn-ZSM-11 [85a, 104], V-EU-1, V-THETA-1 [101] and Cr-ZSM-5 [106] are reported to catalyze arene side-chain oxidation. Oxidation of primary amine and various arylamines even with electron-withdrawing groups to the corresponding nitro compounds is possible with Cr-ZSM-11 [76a]. Oxidation of secondary amines to nitrones [91] and thioethers to sulfoxides and sulfones is possible with V-ZSM-5 [85a].

Redox catalytic applications of AlPOs include selective oxidation of secondary alcohols to ketones with Cr-AlPO₄-5 [106], oxidation of the allylic group to unsaturated ketones with Cr-AlPO₄-5 [107], selective oxidation of alkenes to epoxides with V-AlPO₄-5 [108], selective epoxidation of allylic alcohols with V-AlPO₄-5 [100], phenol hydroxylation with V-ZSM-48 [109], secondary amine oxidation with V-AlPO₄-5 [91] and arene side-chain oxidation with Cr-AlPO₄-5, AFI-AlPO₄-5 and Co-AlPO₄-11 [110]. Leaching of the active metal is a common problem with redox AlPOs. The use of large pore structures for bulky aromatic oxidations is illustrated in the case of V-NCL-1 catalyzed oxidation of naphthalene and trimethylbenzenes [85a, 98]. Zeolites such as V-zeolite- β and V-borosilicate- β are reported for arene side-chain oxidation [111]. Oxidation of ethanethiol and 2-mercaptoethanol to disulfides with O₂ is possible with Co-faujasite [112].

From the examples above, it is clear that oxidation reactions using redox-active molecular sieves is an active area of research for the synthesis of fine chemicals and intermediates. The novel chemistry is possible because of the location of the transition metal ions at specific crystallographic sites in the framework and also the pore structure of microporous materials.

Entrapped molecules and assemblies

Another route to making oxidation catalysts has been to take advantage of the microporosity of zeolites to incorporate catalytically active transition metal complexes, and forms the subject matter of several review articles [113]. Incorporation of homogeneous catalysts into frameworks offers potential advantages. Accessibility of the reactants to the catalytic site is guaranteed because of the porosity. The metal centers should be more stable to degradation from dismutation or autooxidation reactions. Recovery and re-use of the catalyst are also easy with the heterogenized catalysts. One of the first molecules to be encapsulated into zeolite Y was metal phthalocyanine (Pc) which was synthesized using a ship-in-a-bottle strategy via the condensation of dicyanobenzene molecules [114]. Iron Pc complexes in zeolites X/Y have been used as oxidation catalysts for hydrocarbons using iodosylbenzene (PhIO) as oxidant [115]. Although interesting shape selectivities were observed, the turnover numbers were of the order of 6. Jacobs and co-workers improved the performance of the catalyst by using TBHP as oxidant [116]. Turnover numbers as high as 6000 were reported for the oxidation of *n*-octane at low turn-

Figure 14. (a) Structure of a zeolite-entrapped perfluorinated ruthenium phthalocyanine (RuF_{16}Pc) complex used in epoxidation reactions. (b) Comparison of turnover numbers for cyclohexane oxidation using ruthenium phthalocyanine (RuPc), RuF_{16}Pc and zeolite X-entrapped RuF_{16}Pc .

over frequencies (12 h^{-1}). Significant improvement in turnover frequency for oxidation of cyclohexane (198 h^{-1}) was obtained by incorporating the FePc -zeolite into polymeric (PDMS) membranes [117]. The role of the polymer was to promote adsorption of the substrate into the zeolite. Balkus et al. entrapped ruthenium(II) perfluorophthalocyanine in zeolite X by using it as a template during the zeolite X synthesis. The fluorinated ligand is more stable, and a turnover number of 3000 per day in the oxidation of cyclohexane with TBHP was noted [118]. Figure 14a shows the entrapped Ru complex and Figure 14b compares the turnover numbers in the oxidation of cyclohexane for the Ru-Pc complexes in solution with the encapsu-

lated complex, clearly demonstrating the increased turnover numbers for the zeolite-encapsulated complex [118].

Metal complexes of other macrocyclic ligands such as salen, salophen, pyren and acacen (see Figure 4) have also been incorporated into zeolites and some of these have been examined in oxidation reactions [113]. A chiral Mn(III)–salen type of complex entrapped in zeolite EMT made it possible to obtain chiral products in alkene oxidation reactions using NaOCl as the oxidant [119]. As noted earlier, the oxidant in the epoxidation reactions using redox molecular sieves is typically H_2O_2 . Unfortunately, for metal complexes grafted into zeolites, H_2O_2 cannot be used since it decomposes, possibly by a Fenton-type reaction. This is the reason for the use of PhIO or organic hydroperoxides as oxidants. However, De Vos and Bein have reported that H_2O_2 can be used with the Mn complex of the ligand tmtacu (triamine-1,4,7-trimethyl-1,4,7-triazacyclononane) [120]. Higher selectivity using Mn(tmtacu)–zeolite Y was noted for the epoxidation of styrene, cyclohexane and norbornene. Dutta and Das have shown that the zeolite-encapsulated $[(\text{bpy})_2\text{Ru}(\text{OH}_2)_2]^{2+}$ can be oxidized by air to form the oxo complex $[(\text{bpy})_2\text{Ru}^{4+}=\text{O}]^{2+}$, which could oxidize PPh_3 to OPPh_3 [121]. In homogeneous media, the $\text{Ru}=\text{O}$ complex can only be formed electrochemically or by oxidation with Ce^{4+} [121].

The use of zeolite entrapped chiral complexes as enantioselective catalysts has been examined by Corma and co-workers [122]. Both reduction and oxidation chemistry has been explored. The zeolite used was ultrastable zeolite Y, which contains supermicropores of 12–30 Å, allowing for the encapsulation of larger complexes. These larger pores are formed by partial degradation of the framework during the ultrastabilization process. Upon catalytic hydrogenation of prochiral alkenes using Rh(I), Ru(II), Co(II) and Ni(II) chiral complexes of ligands based on L-prolinol, it was noted that the enantioselectivity was higher for zeolitic hosts than silica or unsupported complexes. Moderate enantioselectivity was also noted in the epoxidation reactions of allylic alcohols with TBHP using chiral dioxomolybdenum(VI) complexes derived from L-*trans*-4-hydroxyproline.

Even though the potential use of such entrapped catalytic systems is obvious, in practice there are problems. The reaction rates are often lower owing to the problems with diffusion of the reactants into the zeolite and pore blockage. These reasons have prompted the use of mesoporous materials and are discussed in Section 3.3.2.

Cluster species

Metal oxides on zeolites have also found use as redox catalysts. High-temperature (700–750 °C) dehydroaromatization of methane under nonoxidizing conditions has been explored with a number of zeolitic catalysts modified with transition metal ions. Although coke formation at these high temperatures is a problem, calcined molybdate-impregnated ZSM-5 shows unparalleled activity of up to 8 % methane conversion with 100 % selectivity towards aromatics. Surface studies of these Mo–HZSM-5 catalysts indicate that MoO_3 crystals are on the external zeolite surface [123].

MO_x –zeolites prepared by incorporation of metal complexes followed by mild oxidation offer unique control of activity. Comparison of Cu–ZSM-5 catalysts

prepared from $\text{Cu}(\text{OAc})_2$ and $[\text{Cu}(\text{en})_2]^{2+}$ precursors indicate that the former has higher activity for NO decomposition, whereas the latter is better for methanol conversion to higher hydrocarbons. It has been speculated that these differences in activity may be due to the fact that Cu-ZSM-5 catalyst prepared from $\text{Cu}(\text{OAc})_2$ shows a nearly equal distribution of the copper ions sited near pairs of Al^{3+} (site II) and isolated Al^{3+} ions (site I), whereas the catalyst prepared from $[\text{Cu}(\text{en})_2]^{2+}$ shows most of the copper ions sited near multiple Al^{3+} (site II) after reduction in CO [124].

Applications of cation-exchanged ZSM-5 include ammoximation of alkanes with Co-ZSM-5, water-tolerant oxidation of NH_3 to N_2 with Pd-ZSM-5, low-temperature catalytic combustion of CH_4 with Pd-ZSM-5, wet N_2O decomposition with Co-ZSM-5, NO_x reduction with CH_4 even in the presence of excess O_2 with Co-ZSM-5 and catalytic decomposition of NO in the absence of O_2 with Cu-ZSM-5. In most of these cases, the activity (rate, conversion and/or selectivity) of the redox ZSM catalysts is much higher than when the corresponding metal is supported on traditional oxides [125].

The examples discussed above demonstrate the unique advantages of zeolitic hosts; primarily stemming from highly dispersed exchange sites and the ligating effect of the framework on the cations.

Photoredox chemistry

Active involvement of zeolitic framework in electron-transfer chemistry

It was discovered several decades ago that spontaneous thermal electron transfer from encapsulated aromatic organics to the zeolite framework is possible. Although the exact location of the electron on the framework was not determined, dehydration of the zeolite, the zeolite topology and the nature of the co-cations in the zeolite were found to be important in generating the radical species. $\text{NH}_4\text{-Y}$ zeolite rather than Na-Y was necessary for formation of radical cations of 1,1-diphenylethylene, triphenylamine, quinoline, perylene, aniline and *p*-phenylenediamine [126]. Recent studies have shown that stable, radical cations of α,ω -diphenylpolyenes can be formed thermally on activated Na-ZSM-5 [127].

Photoexcitation of aromatics in zeolites also led to cation radicals, as reported by Iu and Thomas for pyrene and anthracene [128]. Ultraviolet photoexcitation of *trans*-stilbene in NaX formed the *trans*-stilbene radical cation (475 nm) and the zeolite-entrapped electron shows up as Na_4^{3+} (500 nm) [129]. Other organic species that form radical cations in zeolites upon high-energy UV excitation include 4-vinylanisole, *trans*-anethole, several styrenes and di(4-methoxyphenyl)ethylenes [130].

Thomas and co-workers found that high-energy γ -radiation will ionize the zeolite framework, forming holes and electrons [131]. In the presence of intrazeolitic water, hydrated electrons $(\text{H}_2\text{O})_n^-$ were formed, and characterized by their electronic spectra and short lifetimes. Figure 15a shows the transient absorption spectrum (20 ns) of the hydrated electron as a function of water content in zeolite X. For the zeolite with 41 water molecules per pseudo cell, the band at 600 nm was assigned to the hydrated electron. Upon decreasing the water content to 31 molecules per

pseudo cell, two bands at 540 and 750 nm were observed and assigned to a cation cluster trapped electron (Na_4^{3+}) and the hydrated electron, respectively [132]. Reactions of $(H_2O)_n^-$ with O_2 , N_2O and viologens were studied. In the case of methylviologen (MV^{2+}), electron transfer to form the MV^{+} radical occurred with the kinetics of ET being determined by the degree of hydration of the zeolite. From the quenching of the lifetime of $(H_2O)_n^-$ as a function of MV^{2+} , it was determined that the diffusion coefficient (D_e) of the hydrated electron through the zeolite medium is $1.2 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ for $(H_2O)_{31}^-$ and $3.5 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ for $(H_2O)_{38}^-$. The de-

crease in D_e with water content was considered to be a reflection of the activation barrier for the electron to pass from one supercage to another across a 7.4 Å window.

The holes generated by the high-energy radiation also reacted with organic molecules such as pyrene and methylviologen (MV^{2+}) to form radical cations [131]. Figure 15b shows the transient absorption spectrum of an MV^{2+} -zeolite Y after the electron pulse [131]. The bands at 390 and 600 nm are typical of MV^{+} , but the band at 470 nm that grows with time is typical of the hydroxyl adduct of MV^{2+} . Formation of OH^\bullet was explained by the following reaction:

Thus, exposure of zeolites to high-energy radiation leads to the formation of holes and electrons, both of which react with water to produce OH^\bullet and hydrated electrons.

Zeolite frameworks have also been reported to act as an electron donor via charge-transfer (CT) interactions. Yoon and co-workers examined the electronic spectra of a series of alkali metal ion-exchanged faujasitic zeolites containing about one MV^{2+} per eight supercages [133]. A new electronic band around 250–270 nm was observed in only the dehydrated zeolite X/Y samples, with the band red-shifting with increasing electropositivity of the metal ion: Li^+ (256 nm), Na^+ (258 nm), K^+ (263 nm) Rb^+ (265 nm) and Cs^+ (268 nm) (Figure 16) [133]. This band was assigned to a CT transition from the zeolite framework to methylviologen. A linear correlation, indicative of Mulliken's CT theory, was found between the energy of the CT band and the average charge on the framework oxygen atom, as calculated by Sanderson's electronegativity principle. This example represents a unique feature of the zeolite not only in the sense that it acts as an electron donor, but also because the degree of donation is tunable by the ion-exchanged cation. A related example of the zeolite acting as an electron donor is the detection of MV^{+} with lifetimes of

Figure 16. Electronic spectra of dehydrated MV^{2+} -alkali metal ion-exchanged zeolite Y as a function of alkali metal ion.

several hours upon UV photoexcitation of MV^{2+} in Rb- and Cs-zeolite Y [134]. Framework oxygen atoms were proposed as the electron-donating sites.

Electron-transfer reactions between entrapped species in zeolites

Transient spectroscopic studies

Extensive studies have been carried out on ET reactions between guest molecules in zeolites. The reaction of interest is

where A represents the electron acceptor and D the donor. In photoinitiated ET reactions, the major issues concern the efficiency of the forward ET process, the rate of the back ET reaction and the long-term stabilization of the charge-separated pairs. In photoinitiated ET reactions, the strong driving force for the back ET reaction limits the lifetime of the charge-separated states and thereby the usefulness of the photochemical process. Several review articles have appeared in the last few years in this research area [135]. We shall first examine the role of the zeolite as a host in influencing the dynamics of the photoelectron transfer reactions. Transient spectroscopic measurements are necessary to monitor the fate of charge-separated species. The time resolution of these experiments is controlled by the pulse width of the interrogating lasers and can be as brief as hundreds of femtoseconds. Considering that the zeolite matrix is a powder, transient studies typically involve diffuse reflectance spectroscopy, which provides information on the electronic spectra of the reactant/product species [136]. We discuss below three cases that clearly demonstrate the influence of the zeolite on the dynamics of ET reactions.

Aromatic hydrocarbons as donors: Charge-transfer complexes between aromatic hydrocarbons and bipyridinium in zeolites have been extensively studied [137]. Typically, MV^{2+} -exchanged zeolites are colorless but develop intense colors upon introduction of arene donors. This is reflected in the absorption spectra by the appearance of new CT bands, whose wavelength maxima relate well to the ionization potential of the donors, as expected from Mulliken's CT theory. Photoexcitation within the CT band of the anthracene (ANT)- MV^{2+} complex in zeolite Y with a 25 ps laser pulse led to the appearance of bands at 620 and 730 nm, which were assigned to the radical species $MV^{+\bullet}$ and $ANT^{+\bullet}$, respectively. The decay of these signals by the thermal back ET process occurred with a rate constant of $2.9 \times 10^9 \text{ s}^{-1}$, which was at least an order of magnitude slower than in acetonitrile ($4 \times 10^{10} \text{ s}^{-1}$). Interestingly, the signal due to the radical cations persisted beyond 4 ns, and for experiments done on the microsecond time-scale, residual absorptions were found beyond 1 ms. In zeolite L, which has channels of 7 Å, the decay rates were faster, e.g. for ANT-DQ $^{2+}$ (2,2'-bipyridinium ion) the rate constant was $2.2 \times 10^{10} \text{ s}^{-1}$ compared with $4.7 \times 10^9 \text{ s}^{-1}$ in zeolite Y. The three different decay regimes and the role of the zeolite topology on the back ET process have been explained as arising from electrostatic interactions with the zeolite. The radical ion pairs generated upon photoexcitation of the arene-pyridinium complexes are posi-

tively charged or neutral in all the cases that were examined. Since, the zeolite framework is negatively charged, Coulombic attraction of the radicals toward the zeolite walls will separate the charge pairs. The different decay regimes have been explained in terms of the acceptor and donor radicals being at different distances within the zeolite cages. Similar arguments justify that the back ET in zeolite L was faster than that in zeolite Y, because of the smaller size of the channels (7 Å) in zeolite L compared with the zeolite Y supercages (13 Å).

Charge-transfer complexes of neutral molecules in zeolites have also been examined. Transient experiments with 1,2,4,5-tetracyanobenzene (TCNB) as acceptor and arene donors have been reported. For naphthalene, transient absorption bands centered at 470 and 680 nm due to TCNB^{•-} and naphthalene radical were observed [138]. The decay was found to be biphasic and was 10 times slower in dehydrated zeolite Y than in the hydrated sample, indicating a strong interaction with the framework.

Sensitized electron-transfer reactions: The influence of the zeolite host on photo-sensitized ET reactions has also been investigated for a number of systems. Ramamurthy and co-workers found that the radical cation of *trans*-anethole was formed upon photoexcitation of 2,3-dicyanonaphthalene or 9-cyanoanthracene as sensitizers in zeolite NaX with 355 nm radiation [130a]. Figure 17 shows the transient diffuse reflectance spectra of the *trans*-anethole cation for two different loadings. From the decay of the signal, it was concluded that the radical cation was long-lived (half-lives in excess of 10 μs), and entrapment in the zeolite was slowing down the back ET reaction [130a].

Tris(bipyridyl) complexes of ruthenium: Another photosensitizer system that has been extensively studied in zeolites is tris(2,2'-bipyridine)ruthenium(II) [Ru(bpy)₃]²⁺,

Figure 17. Transient spectra of nitrogen purged 2,3-dicyanonaphthalene ($10 \mu\text{mol g}^{-1}$) plus *trans*-anethole (\diamond , $32 \mu\text{mol g}^{-1}$; \bullet , $190 \mu\text{mol g}^{-1}$) in NaX measured $0.6 \mu\text{s}$ after 355 nm excitation. Inset shows decay of the signal at 610 nm for high loading of *trans*-anethole sample.

which has a long-lived (~ 500 – 600 ns) metal-to-ligand CT (MLCT) state, populated via visible excitation (peaked around 450 nm). Several transient spectroscopic studies have been reported for the $\text{Ru}(\text{bpy})_3^{2+}$ –bipyridinium photosensitized ET in zeolites. Mallouk and co-workers were the first to investigate the kinetics of photoelectron transfer from $\text{Ru}(\text{bpy})_3^{2+}$ on the surface of the zeolite to bipyridinium ions in the zeolite [139]. They linked a tris-ligated bipyridine complex of $\text{Ru}(\text{II})$ via an ethylene unit with a 2,2'-bipyridinium ion (2DQ^{2+}). The positive charge on the DQ^{2+} unit made it possible to exchange the RuL_3^{2+} – 2DQ^{2+} on to the surface of a zeolite that was previously exchanged with benzylviologen (BV^{2+}). The reduction potentials of $^*\text{RuL}_3^{2+}$, 2DQ^{2+} and BV^{2+} are -1.50 , -0.75 and -0.59 V (vs. SCE), respectively. Upon photoexcitation of the zeolite with a 10 ns, 532 nm laser pulse, the transient spectrum showed absorption maxima at 400 and 600 nm, assigned to the radical $\text{BV}^{+\cdot}$ and bleaching of the band at 480 nm due to formation of RuL_3^{3+} . The formation of the Ru^{3+} – $\text{BV}^{+\cdot}$ charge-separated pairs via the ET steps $\text{RuL}_3^{2+} \rightarrow 2\text{DQ}^{2+} \rightarrow \text{BV}^{2+}$ occurred within 100 ns. The back ET rate constant was determined as $2.7 \times 10^4 \text{ s}^{-1}$. The longer spatial separation of Ru^{3+} and $\text{BV}^{+\cdot}$ was suggested as the reason for the slow back ET.

In a more recent study, Mallouk and co-workers investigated the dynamics of ET of a series of $[\text{RuL}_3^{2+}-(\text{CH}_2)_n\text{-viologen}]^{2+}$ on the zeolite surface as a function of the length of the methylene spacer [140]. Several zeolites were examined, including zeolite Y, mordenite and zeolite L. In all cases, the viologen ends of the donor–acceptor pair ion-exchanged into the surface cages/channels of the zeolite, while the RuL_3^{2+} unit remained external to the zeolite. For small values of n (~ 2), the dynamics of the forward ET were too fast to be measured. For longer chains, it was found that the forward ET occurred 1–2 orders of magnitude slower ($\sim 10^8 \text{ s}^{-1}$) than in solution. Two reasons were proposed for this effect. First, the zeolite-exchanged complex has less flexibility than in solution and favorable conformations for ET may be restricted. Second, it was proposed that the ion exchange on to the zeolite surface may have modified the reduction potentials, and thereby the thermodynamic driving force for ET. The conformational argument for slowing of the ET is consistent with the fact that zeolite Y provides the greatest freedom followed by mordenite and zeolite L, and the forward ET rates followed the order zeolite Y > mordenite > zeolite L. The back ET dynamics were found to be complex and the rate constants were derived based on the Alberty model, which assumes heterogeneity of sites and, thereby, rate constants. It was found that for CH_2 spacer lengths ($n = 5$), the lifetime of $\text{Ru}(\text{III})$ –viologen $^{+\cdot}$ could be 10^5 times longer than in solution. Figure 18 demonstrates the decay of the viologen radical formed on a mordenite sample, measured by transient diffuse reflectance spectroscopy [140]. The inset shows the rapid rise in the $\text{MV}^{+\cdot}$ signal, followed by a slow decay. Such a large increase in lifetime was explained by a combination of slow back ET, and lateral ET between $\text{Ru}^{3+}/\text{Ru}^{2+}$ and $(\text{viologen})^{2+}/(\text{viologen})^{+\cdot}$ pairs, which would move the charges further apart.

Dutta and co-workers focused on the completely intrazeolitic $\text{Ru}(\text{bpy})_3^{2+}$ and bipyridinium ion systems [141]. Three N,N'-dialkyl-2,2'-bipyridinium ions and methylviologen (4,4'-bipyridinium ion) with reduction potentials varying from -0.37 to -0.65 V (vs. NHE) were studied. For the 2,2'-bipyridinium salts (members

Figure 18. Time-resolved diffuse reflectance spectra 12–150 μ s after excitation from 532 nm laser pulse for $\text{Ru}(\text{bpy})_3^{2+}$ – $(\text{CH}_2)_5\text{-MV}^{2+}$ on mordenite. Inset shows the decay of methylviologen radical followed at 400 nm.

of the diquat family), two, three and four CH_2 bridging units, abbreviated 2DQ^{2+} , 3DQ^{2+} and 4DQ^{2+} , respectively, were examined. Because of the limitations of the time-resolved diffuse reflectance instrument, only a lower limit of the forward ET rate ($>10^7 \text{ s}^{-1}$) constant from $\text{Ru}(\text{bpy})_3^{2+}$ to the bipyridinium ion was obtained. The back ET from the photogenerated bipyridinium radical ions to $\text{Ru}(\text{bpy})_3^{3+}$ was monitored at different intrazeolitic bipyridinium concentrations. At low loadings of bipyridinium ions (one per 10–15 supercages), the transient signal between 360 and 390 nm had contributions from both $\text{Ru}(\text{bpy})_3^{2+}$ and the bipyridinium radical ions, since the bipyridinium ion concentration was not high enough to quench all of the $\text{Ru}(\text{bpy})_3^{2+}$. The decay of this signal (360–390 nm) could be fitted to the sum of two exponentials, representing the disappearance of unquenched $\text{Ru}(\text{bpy})_3^{2+}$ and the back ET from the bipyridinium radical ions to $\text{Ru}(\text{bpy})_3^{3+}$. The rate constants for the back ET for 2DQ^{2+} , MV^{2+} , 3DQ^{2+} and 4DQ^{2+} were found to be 4.0×10^4 , 1.7×10^4 , 1.1×10^4 and $7.3 \times 10^3 \text{ s}^{-1}$, respectively. The decrease in the ET rates with increasing driving force for the reaction indicates that the ET is occurring in the Marcus inverted region. At high loadings of the bipyridinium ions (1.2–1.7 molecules per supercage), the bipyridinium radical ions were considerably longer lived, as shown in Figure 19, and a simple exponential decay no longer described the loss of the bipyridinium radical signal [141]. A model that allowed for electron exchange processes between bipyridinium ions to compete with the back ET was necessary. The basis of the kinetic model is shown in Figure 20 and made it possible to extract the back ET rate constant (k_b) at high loadings along with the rate constants for electron hopping (k_{hop}) and a second-order electron (bipyridinium radical)–hole ($\text{Ru}(\text{bpy})_3^{3+}$) recombination process (k_2). For the series 2DQ^{2+} , MV^{2+} , 3DQ^{2+} and 4DQ^{2+} with high loading, the back ET rate constants were 2.5×10^5 , 9×10^4 , 1.8×10^5 and $1.2 \times 10^5 \text{ s}^{-1}$, respectively. In the high

Figure 19. Decay of MV^{2+} for intrazeolitic $Ru(bpy)_3^{2+}-MV^{2+}$ -zeolite Y for high MV^{2+} loading. Inset shows the decay at shorter times and solid lines indicate best fit using the model shown in Figure 20.

Figure 20. Model of the electron transfer process in $Ru(bpy)_3^{2+}-MV^{2+}$ -zeolite Y.

loading case, longer lived charge separation was observed because of the presence of a route for charge propagation by electron hopping via the densely packed viologen molecules.

Steady-state photolysis studies

The above discussions on the transient spectroscopic studies of photoelectron transfer in zeolites clearly show that the dynamics of the ET can be strongly influenced by the host matrix. In particular, the energy-wasting back ET in all cases appears to be slowed inside the zeolite. Several research groups have taken advantage of the slower back ET in zeolites to develop novel synthetic schemes, and also to design systems that result in permanent charge separation. These experiments are typically done by steady-state photolysis followed by spectroscopic and/or chromatographic analysis of the products.

Synthetic schemes: Ramamurthy and co-workers have exploited the stabilization of arylalkene cation radical in zeolite X formed via photosensitized ET to examine the dimerization reaction of arylalkenes [130a]. Various photosensitizers, including cyanoaromatic compounds and quinolium and acridinium ions, have been examined. The radical cations react with the precursor alkenes to form the dimers shown in Figure 21 [130a]. Besides the role of the zeolite in stabilizing the radical cation by limiting the back ET, the spatial constraints in the zeolite also influenced the product distribution as compared with studies in homogeneous solution. Both *cis,syn* and *trans,anti* dimers were formed in solution and in the zeolite. However, in all cases the zeolite preferentially stabilized the more spherical *cis,syn* isomer rather than the elongated *trans,anti* dimer, reflecting the spherical geometry of the supercage [130a].

Permanent charge separation

Arene–bipyridinium CT complexes: As discussed above, long-lived charge-separated species were observed by transient spectroscopy upon excitation into the CT band of arene–bipyridinium complexes in Na-X zeolites. Interestingly, if the arene contained a CH₃ group (ArCH₃), as in pentamethylbenzene, mesitylene, durene, prehnitene and methylnaphthalene, and K⁺, Rb⁺ or Cs⁺ zeolite X were used as the host, photoexcitation led to permanent stabilization of the bipyridinium cation radical [135e]. Explanation of this effect hinges on the fact that the cation radical of the methylated arenes are acidic and that the zeolite framework is basic with ion exchange of the more basic alkali metal ions. The following scheme demonstrates the process (ZO represents the zeolite framework):

The CH₂Ar[·] radical can dimerize, leaving a steady-state population of MV⁺⁺. This example shows that the zeolite can be an active host and influence ET re-

Figure 21. Reaction products of the photosensitized dimerization reactions of arylalkenes in NaX compared with solution studies.

actions both via electrostatics, leading to long-lived charge-separated species, and as a reactant in promoting permanent charge separation.

Ru(bpy)₃²⁺–bipyridinium system: From the transient studies on both zeolite-encapsulated and surface $\text{Ru}(\text{bpy})_3^{2+}$ –bipyridinium discussed above, it is clear that the zeolite promotes long-lived charge-separated states. Several strategies have been reported in translating the long-lived charge separation to permanent charge separation [142]. Dutta and co-workers surrounded the encapsulated $\text{Ru}(\text{bpy})_3^{2+}$ in zeolite Y with a 2,2'-bipyridinium ion (4DQ^{2+} , $E^\circ = -0.65$ V vs. NHE) and in turn suspended the zeolite in a solution of propylviologen sulfate (PVS, $E^\circ = -0.4$ V vs. NHE). Upon photoexcitation of the suspension in a deaerated environment, the aqueous solution turned blue and the absorption spectrum of the solution indicated the presence of $\text{PVS}^{\bullet+}$ radical cation. The model used to explain the data is shown in Figure 22 [142b]. As was pointed out in the section on transient spectroscopy of $\text{Ru}(\text{bpy})_3^{2+}$ –bipyridinium (high loading) zeolites, the initial process of ET quenching of the $\text{Ru}(\text{bpy})_3^{2+}$ system leads to the formation of the bipyridinium radical cation. Electron hopping can occur between neighboring bipyridinium molecules,

Figure 22. Model of permanent charge separation for the $\text{Ru}(\text{bpy})_3^{2+}$ – DQ^{2+} –PVS system.

leading to long-lived charge separation. If this charge migrates to the surface of the zeolite, then a directional ET to PVS can occur. The formation of $\text{PVS}^{\bullet-}$ will lead to repulsion from the zeolite framework and thereby permanent charge separation. Support for the electron hopping argument between the viologen molecules in neighboring cages is provided by a recent report [143]. It was found that a MV^{2+} –zeolite Y sample upon treatment with $\text{Na}^+\text{Mn}(\text{CO})_5^-$ turned blue, the characteristic color of $\text{MV}^{\bullet+}$, even though $\text{Mn}(\text{CO})_5^-$ cannot penetrate into the zeolite cages. The conversion of intrazeolitic MV^{2+} to $\text{MV}^{\bullet+}$ was quantitative. Electron migration into the zeolite must proceed through charge hopping after the surface MV^{2+} has been reduced by $\text{Mn}(\text{CO})_5^-$.

The problem with the $\text{Ru}(\text{bpy})_3^{2+}$ – 4DQ^{2+} zeolite Y, PVS solution system was its limited efficiency (quantum yield = 5×10^{-4}). This was related to both the back ET (even though it is slowed in the zeolite) and the ability of the charge to move to the surface by electron hopping. Improvements in both these areas have been reported. Kincaid and co-workers focused on influencing the back ET by adding a donor molecule in a cage neighboring the one containing the $\text{Ru}(\text{III})$ species and noticed a four-fold increase in the charge separation [142c, d]. Figure 23a shows the scheme of their ET process. The novelty of their system was the controlled intrazeolitic synthesis in which two molecules have been placed by design in neighboring supercages. Upon photoexcitation of $\text{Ru}(\text{bpy})_2\text{bpz}^{2+}$ in the zeolite, ET to DQ^{2+} occurs. The back ET from $\text{DQ}^{\bullet+}$ to $\text{Ru}(\text{bpy})_2\text{bpz}^{3+}$ is intercepted because of the ET from the neighboring $\text{Ru}(\text{mmb})_3^{2+}$ to $\text{Ru}(\text{bpy})_2\text{bpz}^{3+}$. As a result, there is increased efficiency of permanent charge separation ($\text{PVS}^{\bullet-}$). Figure 23b compares the $\text{PVS}^{\bullet-}$ yield for the adjacent cage system (AC), $\text{Ru}(\text{bpy})_2\text{bpz}^{2+}$ or $\text{Ru}(\text{mmb})_3^{2+}$ in zeolites

as lone electron donors and a mechanical mixture (MM) of two zeolites containing $\text{Ru(bpy)}_2\text{bpz}^{2+}$ and Ru(mmb)_3^{2+} .

Castagnola and Dutta investigated the use of nanocrystalline zeolites with high surface area as hosts [18]. The strategy to increase photochemical efficiency was

based on the fact that a larger fraction of the charge can migrate to the surface of nanocrystallites, and be transferred to the PVS in solution, as per the model in Figure 22. A patent procedure was followed to synthesize 250 nm aggregates of 30 nm crystallites of zeolite X. A low-temperature aging step and addition of sucrose to the reaction mixture were required to achieve optimum quality of crystals. Conventional ship-in-a-bottle synthesis of $\text{Ru}(\text{bpy})_3^{2+}$ in the cages of these nanocrystallites resulted in considerable framework degradation, with only 10 % of the crystallinity in the original crystals being retained. The degradation occurred owing to exposure to mild acidity and thermal treatment during the synthesis of $\text{Ru}(\text{bpy})_3^{2+}$. The procedure was modified by avoiding acidity in the initial ion exchange of $\text{Ru}(\text{NH}_3)_6^{3+}$, resulting in a $\text{Ru}(\text{bpy})_3^{2+}$ -zeolite with 75 % of the crystallinity retained. Acidity generated during conversion of $\text{Ru}(\text{NH}_3)_6^{3+}$ to $\text{Ru}(\text{bpy})_3^{2+}$ was thought to be responsible for the degradation. A third procedure starting with the highly air-sensitive $\text{Ru}(\text{NH}_3)_6^{2+}$ resulted in the formation of $\text{Ru}(\text{bpy})_3^{2+}$ -zeolite with about 90 % crystallinity. In all three procedures, the $\text{Ru}(\text{bpy})_3^{2+}$ molecules were entrapped within the framework. Ion exchange of viologen molecules and the fluorescence quenching of photoexcited $\text{Ru}(\text{bpy})_3^{2+}$ by intrazeolitic viologen increased with increase in zeolite crystallinity. Photolysis of $\text{Ru}(\text{bpy})_3^{2+}$ -viologen-zeolite in the presence of zwitterionic propylviologen sulfonate in solution also showed an increase in permanent charge separation efficiency as the crystallinity of the $\text{Ru}(\text{bpy})_3^{2+}$ -zeolite increased (Figure 24a) [18]. Because of the increased surface-to-volume ratio of the nanocrystallites compared with conventional micron-sized zeolite Y, the photochemical charge separation efficiency was found to be a factor of two better with the small crystallites (Figure 24b) [18].

These examples demonstrate that within the last few years, the sophistication for designing novel photochemical assemblies in zeolites has increased considerably and has resulted in our getting closer to architectures that provide permanent charge separation. The challenge continues to be in increasing the photochemical efficiency of the process.

Other permanent charge separation schemes: Fukuzumi and co-workers reported that permanent charge separation could be accomplished in a system consisting of Fe^{2+} /10-methylacridinium (AcrH^+)-zeolite Y sample suspended in an acetonitrile solution of 7,7,8,8-tetracyanoquinodimethane (TCNQ) [144]. A schematic diagram of their charge separation process is shown in Figure 25. Upon photoexcitation of AcrH^+ , its singlet excited state is quenched by intrazeolitic Fe^{2+} . The AcrH^+ can then transfer an electron to TCNQ in solution across the zeolite-solution interface to form $\text{TCNQ}^{\cdot -}$ in solution [144]. The rate of formation of $\text{TCNQ}^{\cdot -}$ depended on the Fe^{2+} loading of the zeolite. The upper limit of the rate constant was estimated to be $\sim 3 \times 10^{-8} \text{ mol dm}^{-3} \text{ s}^{-1}$ from their data. The back ET was measured by the loss of $\text{TCNQ}^{\cdot -}$ upon interaction with Fe^{3+} -exchanged zeolite Y. A decay rate of $1.5 \times 10^{-10} \text{ mol dm}^{-3} \text{ s}^{-1}$ was found, which is several orders of magnitude smaller than the rate of formation of $\text{TCNQ}^{\cdot -}$. In solution, the reaction between $\text{TCNQ}^{\cdot -}$ and Fe^{3+} is immediate, as expected from the reduction potentials. Thus, reaction between Fe^{3+} in the zeolites and $\text{TCNQ}^{\cdot -}$ in solution is drastically slowed because the $\text{TCNQ}^{\cdot -}$ is repelled by the negatively charged zeolite framework.

Photochemical oxidation of hydrocarbons in zeolites

Over the last several years, considerable research has been done on using zeolite hosts for examining oxidation reactions of hydrocarbons, using O₂ as the oxidant.

Singlet oxygen: Intrazeolitic singlet oxygen (¹O₂) can be generated with an ion-exchangeable sensitizer such as thionin in the zeolite. Drying of the zeolite sample is crucial to get the thionin in its monomeric form. Upon photoexcitation of the monomer, emission from singlet oxygen can be observed. The reaction of ¹O₂ with

Figure 25. Schematic representation of the electron transfer process for Fe^{2+} - $AcrH^+$ -zeolite Y with TCNQ in solution.

alkenes containing more than one distinct allylic hydrogen results in formation of several hydroperoxides in a homogeneous medium [145]. The role of the zeolite entrapment on the product distribution has been examined [146]. It was found that with most alkenes, a single hydroperoxide was formed within zeolite Na-Y. With 1-methylcycloalkenes, 100 % of the product was the result of the hydroperoxide formed by abstraction of the methyl protons. In solution, this product is usually formed in the lowest yield amongst three possible products. Two possible roles of the zeolite have been proposed for the high selectivity: control of the conformation of the alkene and/or polarization of the alkene. In both cases, the extra-framework cation of the zeolite was considered to play a major role, with smaller cations having a stronger effect on the selectivity.

Oxygen activated by charge-transfer reaction: It has been known since the 1950s that charge-transfer complexes of alkanes, alkenes or arenes with O_2 can be formed in O_2 -saturated hydrocarbon liquids or at high pressures of O_2 in the gas phase [147]. These charge-transfer bands, especially with small organic molecules, occur in the UV region and upon excitation at these wavelengths, photo-oxidation is observed with formation of many products. The initial step is the formation of superoxide ($O_2^{\bullet-}$), followed by proton transfer from the organic radical to form an HO_2^{\bullet} radical. The complex distribution of products is the result of secondary reactions of the radical intermediates.

Frei and co-workers reported that product distributions were much simpler if photoexcitation of hydrocarbon- O_2 complexes were carried out in zeolites [148].

Figure 26. (a) UV-Vis transmittance spectra of $\text{O}_2\text{-N}_2/\text{NaY}$ (1) and $\text{DMB/O}_2\text{-N}_2/\text{NaY}$ (2) for films of large Na-Y crystals at 253 K. Bars indicate the estimated DMB-O_2 absorption for scattered and unscattered transmitted light. (b) Proposed mechanism for the formation of 2,3-dimethyl-3-hydroperoxy-1-butene in $\text{DMB/O}_2\text{-NaY}$.

Several reasons were proposed to explain the cleaner chemistry. First, the electrostatic fields (0.3 and 0.9 V \AA^{-1} for Na-Y and Ba-Y, respectively) in the zeolite stabilize the hydrocarbon- O_2 charge transfer, thereby shifting the transition to visible wavelengths. Second, the use of visible excitation suppresses the secondary photochemistry rampant with UV light. Third, the steric constraints imposed by the zeolite promote product selectivity. This chemistry can be demonstrated by the reaction of 2,3-dimethyl-2-butene (DMB). Figure 26a shows the electronic spectrum

corresponding to the charge-transfer complex of DMB with O_2 in optically transparent crystals of large Na-zeolite Y on a CaF_2 support [148]. Trace 1 is the background spectrum in O_2 and trace 2 is with DMB. The difference between traces 1 and 2 shows an onset of absorption between 600 and 700 nm and a flat maximum between 400 and 500 nm. The red shift of the absorption band into the visible region in the zeolite as compared with solution was proposed to occur because of stabilization of the charge-transfer complex via the electrostatic fields in the zeolite. Visible excitation into the DMB- O_2 charge-transfer band at $-50^\circ C$ leads primarily to the formation of 2,3-dimethyl-3-hydroperoxy-1-butene, as identified by infrared spectroscopy. The proposed mechanism of formation of the hydroperoxide is shown in Figure 26b. The hydroperoxide intermediate was found to be common at the lower temperatures for a variety of substrates that were studied, including alkenes, alkyl-substituted benzenes and alkanes. Upon warming to room temperature, the hydroperoxide was found to be converted to more stable products, e.g. in the case of propylene oxidation, acrolein was formed. Frei and co-workers have recently summarized their photo-oxidation research on hydrocarbons [148d].

Several other research groups have also published papers in this area. A recent study by Larsen, Grassian and co-workers was focused on 1-alkene oxidation in a series of Ba-loaded zeolites, including zeolites X/Y, Z5M-5 and Beta [149]. They noticed that the intermediate hydroperoxide formation leads to selective product formation as long as temperatures are kept below $-20^\circ C$. At ambient temperature, a series of products can form, resulting in loss of selectivity. For example, in 1-butene photo-oxidation, mixtures of aldehydes, ketones, epoxides and alcohols were formed. Figure 27 shows the difference infrared spectra before and after photolysis of 1-butene and oxygen in Ba-Y. Comparison of the photolyzed samples (traces a, b and c) with that of methyl vinyl ketone (d) shows that several additional bands are observed [149]. NMR analysis of $CDCl_3$ extracts of the photolyzed samples showed that in addition to methyl vinyl ketone, crotonaldehyde, propionaldehyde, acetaldehyde, butyraldehyde, epoxybutane and 2-butanone are also formed. If acidic sites were present on the zeolite, then polymerization occurred. Thus, the generality of the photo-oxidation reactions in generating specific products can be limited because of the thermal reactions at ambient temperature and polymerization reactions. The reaction rates of the photo-oxidation reactions depended on the excitation wavelength. Since the intensity of the hydrocarbon- O_2 charge-transfer band increases at shorter wavelengths, the rate of photoproduct formation was found to increase, but the selectivity towards specific products decreased. For example, upon excitation of the propylene- O_2 complex at $\lambda > 285$ nm, short-chain saturated aldehydes (acetaldehyde, formaldehyde and propionaldehyde) were formed through a competing dioxetane chemistry (as compared with hydroperoxide).

Kojima and co-workers also examined the photo-oxidation of stilbenes in zeolite Y [150]. The presence of O_2 in the stilbene-NaY sample led to a red-shifting of the tail end of the diffuse reflectance spectrum and was assigned to the charge-transfer complex with O_2 . Upon excitation at 313/366 nm, both *cis*- and *trans*-stilbene undergo photo-oxygenation to form benzaldehyde. Phenanthrene, the expected product from the $[2 + 4]$ cycloaddition reaction of excited *cis*-stilbene, was also formed. The details of the mechanism leading to benzaldehyde and phenanthrene

Figure 27. Difference infrared spectra (before and after photolysis) of 1-butene and oxygen in BaY. Figure 28. Mechanism of benzaldehyde and phenanthrene generation via photooxygenation of *cis*- and *trans*-stilbene within NaY.

formation are shown in Figure 28 [150]. It was noted that polymeric and bulky products were also formed via side reactions, and could not be extracted from the zeolite.

Stabilization via encapsulation

The geometric constraints and the immobilization of molecules in the zeolite supercages give rise to novel ET chemistry that is not observable in fluid media. We discuss two examples of such reactions. 2,4,6-Triphenylpyrylium ion (TP^+) can be synthesized inside zeolite Y supercages by a ship-in-a-bottle approach [151]. The

Figure 29. (a) Mechanism for the photo-oxidation of water by TP^+ . (b) TRDR spectrum of $\text{TP}^+-\text{MV}^{2+}-\text{Y}$ system 10 μs after 355 nm laser excitation: (i) and (ii) correspond to the bleaching of TP^+ ground state, (iii) is assigned to the $\text{MV}^{2+}-\text{OH}^\bullet$ adduct and (iv) is the absorption of TP^\bullet .

TP^+ molecule is unstable in water, but appears to be indefinitely stable in hydrated zeolite. The hydrolysis of TP^+ would require an intermediate state in which the phenyl substituent is displaced out of the molecular plane. This geometry cannot be accommodated in the zeolite cage, thus conferring stability to the TP^+ , and has led to some interesting photochemical studies. Upon photoexcitation of entrapped TP^+ , $^3\text{TP}^+$ is formed which has the appropriate potential to oxidize water and eventually results in the formation of OH^\bullet , as shown in Figure 29a [151]. The formation of OH^\bullet has been confirmed by trapping it as a DMPO adduct and investigating its EPR spectrum. Reactions of the OH^\bullet radical with ion-exchanged MV^{2+} have been studied. Figure 29b shows the transient diffuse reflectance spectrum 10 μs after photoexcitation of $\text{TP}^+-\text{MV}^{2+}-\text{Y}$ with a 355 nm laser pulse. The band marked (iii) is characteristic of the $\text{MV}^{2+}-\text{OH}^\bullet$ adduct [151]. The photocatalytic formation of OH^\bullet has also been exploited in pesticide degradation.

The reaction of water with low-loaded $[\text{Ru}(\text{bpy})_3]^{3+}$ entrapped in zeolite Y has been reported [152]. Since translational mobility of the Ru molecules cannot occur in the zeolite, the multimolecular degradation step observed in solution is no longer possible. Instead, O_2 was found to be formed from the reaction of $[\text{Ru}(\text{bpy})_3]^{3+}$ with water. It was possible to examine the evolution of this reaction at various pHs by spectroscopic methods, such as EPR, diffuse reflectance and Raman spectroscopy. Figure 30 shows the evolution of the diffuse reflectance spectra after exposure of $[\text{Ru}(\text{bpy})_3]^{3+}$ -zeolite Y to water at pH 7 [152]. Trace e is the spectrum of the

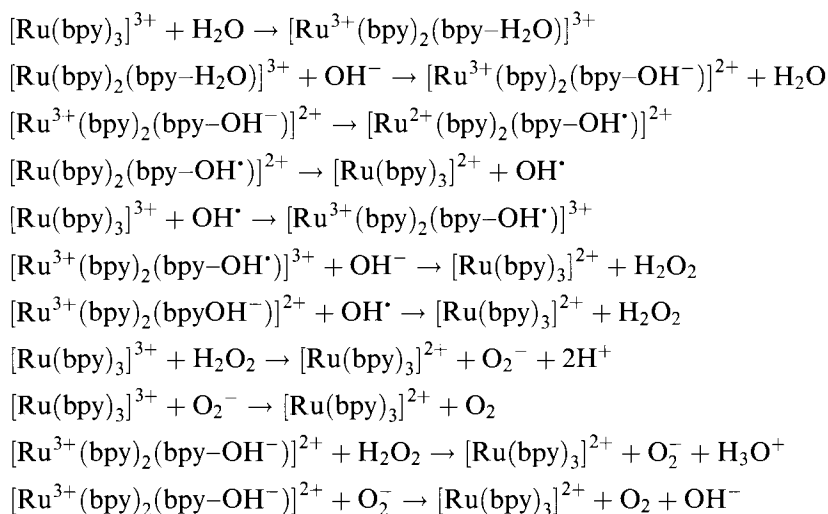

Figure 30. Diffuse reflectance spectra of $\text{Ru}(\text{bpy})_3^{3+}$ -zeolite-Y exposed to pH 7 deionized water for (a) 0, (b) 1, (c) 10 and (d) 42 h. Spectrum (e) is the spectrum of the initial $\text{Ru}(\text{bpy})_3^{2+}$ -Y.

$\text{Ru}(\text{bpy})_3^{2+}$ -zeolite Y used as the starting material for generation of $\text{Ru}(\text{III})$. Upon oxidation by Cl_2 , spectrum a is obtained with bands at 420 and 660 nm, typical of $\text{Ru}(\text{bpy})_3^{3+}$. With time, the band of $\text{Ru}(\text{bpy})_3^{2+}$ at 450 nm recovers. The intensity around 850 nm initially increases and then decreases. Bands in this region are typical of the hydroxylated complexes formed by water attack on the bpy ligands of $\text{Ru}(\text{bpy})_3^{3+}$. The overall mechanism for reaction of water with $\text{Ru}(\text{bpy})_3^{3+}$ was proposed to be as follows:

In the zeolite, owing to the lack of multimolecular degradation, oxidation of water by $[\text{Ru}(\text{bpy})_3]^{3+}$ becomes possible. The reaction is slow, and hydroxyl radicals, hydrogen peroxide and superoxide are created as intermediates. In plant photosynthesis, an Mn-based water-splitting catalyst system in which the reaction with water only occurs after four electrons have been stored in the water-splitting enzyme

complex [153] ensures that reactive oxygen metabolites are not formed. Development of catalysts is required in order to couple the conversion of intrazeolitic $\text{Ru}(\text{bpy})_3^{3+}$ with water oxidation and is discussed later.

Photochemical studies with cluster species

Metal clusters: Mallouk and co-workers reported on procedures to generate small particles of Pt inside zeolite L channels, which they used as catalysts for hydrogen formation [154]. The electron transport chain was composed of EDTA as sacrificial electron donor, zinc tetra(*N*-methyl-4-pyridyl)porphyrin (ZnTMPy^{4+}) as sensitizer and methylviologen (MV^{2+}) as electron acceptor. The zeolite host used was zeolite L, which has a one-dimensional tunnel-like structure (Figure 1e). Small Pt clusters were formed inside the zeolite and then loaded with MV^{2+} by ion exchange. Since $[\text{ZnTMPy}]^{4+}$ was too large to penetrate into the 7 Å zeolite L channels, it was ion exchanged on to the zeolite interface. The negatively charged EDTA^{2-} at pH 4 was intimately associated with the porphyrin. Upon photolysis, the singlet state of the porphyrin was quenched by the neighboring intrazeolitic viologen molecules. The sacrificial electron donor EDTA was oxidized by the porphyrin cation, thus stabilizing the MV^{+} radical, which in the presence of Pt catalysts formed H_2 . It was noted that significant H_2 evolution only resulted for high loading levels of MV^{2+} , necessary for close MV^{2+} – ZnTMPy^{4+} contact, as well as charge propagation by hopping into the zeolite, in agreement with the earlier discussions on page 447.

Calzaferri and co-workers have shown that upon illumination of Ag^+ -exchanged zeolite A which also contains occluded AgCl , the Ag^+ ions are reduced and molecular O_2 is formed [155]:

An interesting effect discovered during photolysis was self-sensitization, i.e. with increasing time, new chromophores were produced, which resulted in a bathochromic shift of the transition from the near-UV to the red region. The chromophores were proposed to be Ag_n^{m+} clusters, the ultimate growth of which was controlled by the size of the cavity.

Metal oxide clusters: Ruthenium oxide on zeolites has been studied as catalysts for the photochemical oxidation of water to oxygen. Thermal decomposition of $\text{Ru}_3(\text{CO})_{12}$ on zeolite Y at 170 °C produced Ru metal, which was readily oxidized by air to RuO_2 [156]. Under ambient oxidation conditions, the particles of RuO_2 were smaller than 2 nm and not observable in powder diffraction patterns. Oxidation by air at increasing temperatures led to sintering and growth of RuO_2 crystallites. The morphology of RuO_2 on the zeolite was found to be strongly dependent on the temperature at which air oxidation occurred. For samples prepared by air oxidation at 200 °C, fibrous structures (50 × 5 nm) of RuO_2 are formed. This material was found to be the best catalyst for water oxidation to O_2 by photochemically generated $\text{Ru}(\text{bpy})_3^{3+}$. Figure 31a compares the O_2 produced as a

(a)

(b)

Figure 31. (a) Comparison of oxygen produced by photolysis as a function of time for RuO_2 -zeolite Y prepared by the carbonyl route ($\text{RuO}_x\text{-Y}_{200}$), RuO_2 -zeolite Y prepared by impregnation ($\text{RuCl}_3\text{-Y}$), RuO_2 powder (RuO_2) and Ru metal (Ru). (b) TEM of fibrous RuO_2 on zeolite Y produced by thermal decomposition of $\text{Ru}_3(\text{CO})_{12}\text{-NaY}$.

function of photolysis time for RuO_2 -zeolite Y prepared via the carbonyl route, RuO_2 -zeolite Y prepared by RuCl_3 impregnation, RuO_2 powder and Ru metal. TEM of this material is shown in Figure 31b. It was concluded that the fibrous morphology of RuO_2 provided specific crystal faces that were optimal for the four-electron oxidation of water to O_2 [156].

Titanium oxides have been extensively studied for photocatalytic applications and several examples of TiO_2 -zeolite composites have also been examined. Sample preparation involved ion exchange or impregnation of titanium ammonium oxalate on zeolite Y followed by calcination at 450°C . TS-1, Ti-MCM-41 and Ti-MCM-48 were prepared by hydrothermal synthesis [157]. UV irradiation (260–290 nm) of the catalyst in the presence of a mixture of gas-phase CO_2 and H_2O led to the for-

mation of CH_4 and CH_3OH . The ion-exchanged and framework-substituted catalysts vastly outperformed the impregnated catalyst. Ti-MCM-48 was found to be better than TS-1 and Ti-MCM-41. XANES and EXAFS studies indicated that in the cases of ion-exchanged and framework-substituted catalysts, the Ti atoms are in an isolated tetrahedral environment and are photoluminescent, whereas the impregnated samples have Ti in an octahedral environment as anatase and do not exhibit photoluminescence. The addition of H_2O or CO_2 led to the efficient quenching of photoluminescence and a decrease in the excited-state lifetime. Water and CO_2 were proposed to react with the photoexcited state $(\text{Ti}^{3+}-\text{O}^-)^*$, resulting in decomposition of H_2O and reduction of CO_2 to form species that eventually end up as methane and methanol [157].

Another major application of Ti-oxide species prepared within the zeolite cavities includes the photocatalytic decomposition of environmentally noxious substances into benign compounds. Examples include photodecomposition of chlorophenol [158] and of NO_x into N_2 and O_2 [159]. TiO_2 -loaded MCM-41 shows a much lower apparent activation energy for the photodegradation of acetophenone than that of TiO_2 -loaded zeolite-X, -Y and -A. The differences in reactivity with different frameworks was related to the efficiency of trapping of the photogenerated electrons and/or holes [160].

Electrochemistry

Electrochemistry using chemically modified electrodes is an important area of research, since with modified electrodes, increase in selectivity of particular chemical reactions becomes possible [161]. Considering that the zeolite framework can impart added selectivity via molecular sieving, ion exchange or entrapment, it is not surprising that zeolite-based electrochemistry has been an active area of research for the past 15 years [162]. Research in this area has matured sufficiently that electroanalytical chemistry using zeolite-modified electrodes (ZME) is being extensively pursued, resulting in novel applications, particularly in the area of sensors.

Since zeolites are insulating in nature, it is necessary to design methodology to bring zeolite particles in to close contact with an electronically conducting material. The important strategies for fabricating ZME fall into three categories [162a]:

- 1) dispersing the zeolite crystallites onto a conducting phase, such as carbon paste, carbon polymer or graphite;
- 2) depositing a zeolite coating with a polymer, such as polystyrene or polyethylene oxide, on an electrode surface;
- 3) mechanically contacting a zeolite pellet with a solid electrode, in the presence or absence of carbon.

Three other methods of electrode preparation include photopolymerization of vinyl-saturated zeolites on a Pt electrode [163], direct synthesis of zeolite films on metal supports [164] (although electrochemical studies on this system have not been reported) and the use of agitated suspensions of zeolite, where zeolite particles contact the electrode at random [165].

Figure 32. Cyclic voltammograms of Co^{2+} -Y ZME in the presence of (a) tetrabutylammonium ion and (b) Li^+ as supporting electrolyte ions.

There has been considerable debate about whether intrazeolitic species are electrochemically accessible and recent results on zeolite-encapsulated metal complexes are of interest in this regard. Before we discuss this topic, the role of ion exchange in electrochemical response is discussed. Electroactive transition metal ions can readily be ion exchanged into zeolites. Baker and co-workers reported that a Co^{2+} -zeolite Y-ZME resulted in reduction of cobalt ions if Li^+ was used as the supporting cation in the electrolyte solution, whereas the voltammetric response was absent in the presence of the larger tetrabutylammonium ion (TBA) [166]. Figure 32 compares the voltammetric data for Li^+ and TBA. There are two ways to interpret these data:

- 1) Co^{2+} -zeolite Y + $e^- \rightarrow \text{Co}^+$ -zeolite Y (electrochemistry)
 M^+ (solution) $\rightarrow \text{M}^+$ -zeolite Y (charge balance)
- 2) M^+ (solution) + Co^{2+} -zeolite Y $\rightarrow \text{M}^+$ -zeolite Y + Co^{2+} (solution) (ion exchange)
 $\text{Co}^{2+} + e^- \rightarrow \text{Co}^+$ (electrode)

After much controversy [167], it now appears that whenever ion exchange is possible, mechanism 2 is the primary method by which an electrochemical response is observed in ZME. Much of the sensor-based research we discuss below is based on the principle of ion exchange, followed by electrochemistry.

Still controversial and of significant importance is the electrochemistry with zeolite-encapsulated complexes. Because of the unusual steric constraints and the

novel electrostatic environment within a zeolite, it can be expected that the electrochemical properties of an entrapped complex may differ significantly from that in solution. If so, then the zeolite host affords an incredible opportunity to influence electron transfer chemistry. Because the entrapped complexes are not ion exchangeable, the issue of extracrystalline redox chemistry as with ion-exchangeable cations will not be relevant.

There are several routes by which intrazeolitic electrochemistry can occur.

1) Direct process:

This would be the most direct way to monitor electrochemical properties of the entrapped complex, C^{n+} .

2) Mediated process:

3) Self-exchange:

Evidence for pathway 3 has been provided by the work of Mallouk and co-workers [168]. Using ZMEs, they showed that the rate of charge transfer from the electrode to metallocenes ion exchanged into the bulk of the zeolite was increased at least 10-fold if the surface of the zeolite was covered with $M(\text{bpy})_3^{2+}$ molecules ($M = \text{Ru}, \text{Os}$) [168a]. Charge diffusion from the zeolite surface to the bulk must be occurring by electron exchange. Similar results were obtained for cationic porphyrin molecules on the zeolite surface and viologen molecules within the bulk of the zeolite [168b]. Using electron and energy transfer quenching of zeolite-bound $\text{Ru}(\text{bpy})_3^{2+}$ with viologens and $\text{Os}(\text{bpy})_3^{2+}$ on other zeolite particles, Mallouk and coworkers concluded that intrazeolitic electron transfer was far more likely than reactions in solution after ion exchange of ions from zeolite. The electrolyte concentration in solution plays an important role in this process. It was concluded that if electrolyte concentrations were below 3 mM, as is typical for many electrochemical experiments, then intrazeolitic electron transfer as the primary route needs to be considered [168c]. Pathway 3 will also require migration of an external cation

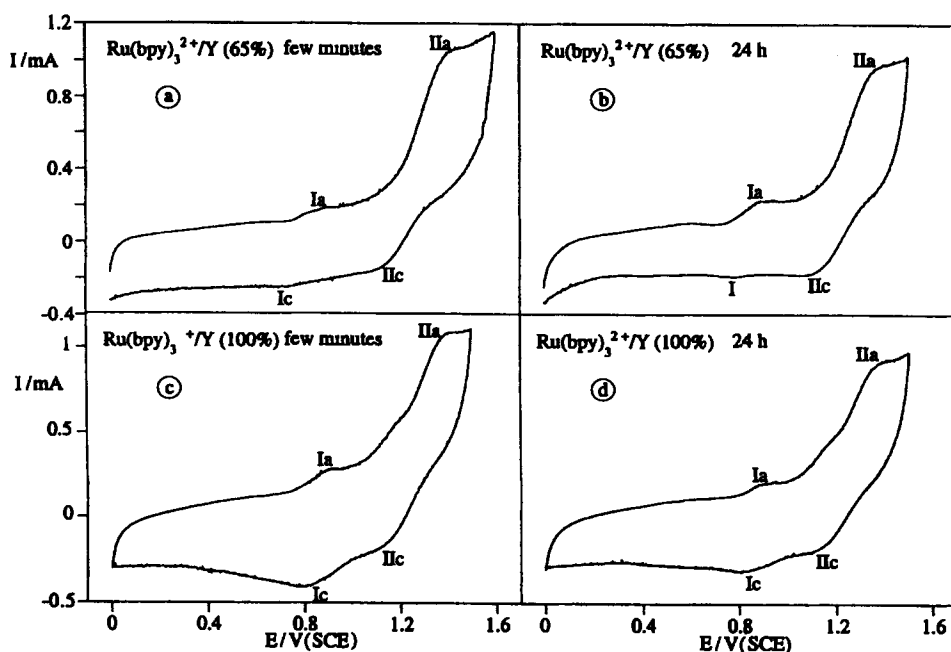

Figure 33. Cyclic voltammograms of zeolite Y-entrapped $\text{Ru}(\text{bpy})_3^{2+}$ at a pressed powder graphite electrode in acetonitrile (0.1 M LiBF_4). Scans taken for both 65 and 100 % loadings a few minutes and 24 h after electrode immersion.

into the zeolite to maintain charge balance. Pathway 2 is feasible, but not particularly interesting from either analysis or electrocatalysis points of view.

Pathway 1 is the most interesting and also the most controversial. There are two schools of thought [169]. The first is that pathway 1 does not occur and any voltammetric signal that is observed arises from complexes that have leached out of the zeolite, either from mechanical degradation during electrode preparation or by some other surface damage of the framework [169a–c]. The second group proposes that intrazeolitic redox does occur and is restricted to the complexes immobilized/entrapped near the surface [169de]. There is general agreement that the interior molecules are not directly accessible.

An example of the nature of electrochemical signal that is observed from zeolite entrapped complexes is shown in Figure 33 [169d]. It shows the cyclic voltammograms for $\text{Ru}(\text{bpy})_3^{2+}$ in zeolite Y at two different loading levels and collected after contact with the electrolytic solution for a few minutes and 24 h. Two redox couples (Ia, Ic) and (IIa, IIc) located at 0.63 and 1.26 V (vs. SCE), respectively, were observed immaterial of the loading or the exposure time [169d]. It was found that only 0.2 % of the entrapped species contributed to the electrochemical signal. $\text{Ru}(\text{bpy})_3^{2+}$ in solution shows a reversible, one-electron, $\text{Ru}^{2+}/\text{Ru}^{3+}$ process at 1.34 V. Two explanations were provided for the appearance of two voltammetric peaks. The first involved the assignment to two species, $\text{Ru}(\text{bpy})_2(\text{H}_2\text{O})_2^{2+}$ in addition to $\text{Ru}(\text{bpy})_3^{2+}$. The second proposed the presence of distorted $\text{Ru}(\text{bpy})_3^{2+}$ species due

to zeolite host–guest interactions. The latter explanation is difficult to rationalize since any influence of the zeolite host should be a continuum rather than two well-defined structural distortions. At the high loading levels examined in this study [65 and 100 % $\text{Ru}(\text{bpy})_3^{2+}$], it is possible that all the bis-complex $\text{Ru}(\text{bpy})_2(\text{H}_2\text{O})_2^{2+}$ has not converted to the tris form, and therefore the presence of two species is likely. Since voltammetric measurements were not reported on $\text{Ru}(\text{bpy})_2(\text{H}_2\text{O})_2^{2+}$ in zeolite Y, assignment of the voltammetric peaks (I, II, Figure 33) to specific molecular species is not possible.

Electroanalysis

Walcarius has recently summarized the status of the field of electroanalysis using ZME and so we shall only briefly highlight some of the basic principles [162c]. Ion-exchange properties of zeolites have been used to preconcentrate analytes, followed by electrochemical detection of the ion-exchanged species, in the analysis of both metal and organic cations. For example, the affinity of zeolite A was used for determining Ag^+ at concentrations of 1 mg L^{-1} in the presence of 10 mg L^{-1} of ions such as Co^{2+} , Mn^{2+} , Ca^{2+} , Pb^{2+} , Cu^{2+} and Ti^{2+} . The ions Bi^{3+} , U^{4+} , Ni^{2+} , Zn^{2+} , Ti^+ , Hg^{2+} and Fe^{3+} showed interference in Ag^+ determination [170a].

Walcarius and co-workers have used methylviologen-exchanged ZME for the detection of alkali metal cations in ion-exchange chromatography [170b–d]. The basis for detection was the ion exchange of the methylviologen out of the zeolite followed by amperometric detection. By using a mobile phase containing tetrabutylammonium bromide (TBABr), they ensured that the electrolyte cation would not enter into the zeolite, thereby minimizing interference with the smaller analyte ions. However, the presence of TBABr interfered with the ion-exchange chromatographic process. The electrolyte was avoided with the use of Cu^{2+} –ZME using carbon pastes. Figure 34 compares the chromatograms for a standard mixture of monovalent ions using a conductivity detector and an unmodified and a copper-modified zeolite carbon paste electrodes.

Zeolite electrodes modified with enzymes include tyrosinase and glucose oxidase and have shown good sensitivity for detection of various phenolic compounds and glucose [171]. It has been proposed that immobilization of the enzyme on the zeolite improved the enzyme activity. In the case of ZME using enzymes, the ion-exchange ability of the zeolite was exploited to immobilize mediator species such as methylphenazonium and TCNQ, which served as a shuttle between the enzymes and electrode. A problem with long-term use is the necessary loss of the mediator from the zeolite via ion exchange with supporting electrolyte cations.

Senaratne and Baker designed a humidity sensor based on the fact that Ag^+ –ZME in dimethylformamide will exhibit no electrochemical response related to Ag^+/Ag reduction, unless water is present to promote ion exchange. Using this technique, 100 ppb of water in DMF could be detected [172].

Electrocatalysis

Zeolite-supported transition metal complexes, such as Mn(III) porphyrin and Cu(II) tetraphenylporphyrin, have been used for the electrocatalytic oxidation of phenols and hydrazine, respectively [173]. Methylviologen-exchanged zeolites have

Figure 34. Use of MV^{2+} -ZME as an electrode for detection of alkali metal ions in ion-exchange chromatography. Detection using (A) a conductivity detector, (B) an unmodified and (C) Cu-modified ZME. Peaks 1–7 correspond to Li^+ , Na^+ , NH_4^+ , K^+ , Cs^+ , Mg^{2+} and Ca^{2+} respectively.

been used for the reduction of oxygen either in the dissolved state or in the gas phase at 425°C [174]. Rolison and co-workers dispersed zeolites in the absence of electrolytes to examine electrocatalysis of a number of systems [175]. Pt-zeolite Y was studied for the electrolysis of water. It was found that extrazeolitic Pt clusters of size 2.5 nm were the most effective catalysts. Another system that Rolison and co-workers examined is the Wacker oxidation of propene in pure water by dispersed Pd(II)- and Cu(II)-modified zeolite Y. Interestingly, both acetone, the normal oxidation product formed by the mechanism shown in Figure 35, and propylene oxide were found as products. Because they noticed partial degradation of the organic substrate, they examined alkali metal ion-exchanged zeolite Y for the detoxification of polychlorinated organic molecules [176]. It was interesting that the use of other solids such as silica, alumina or other zeolites led to oxygenation of the aromatic ring rather than complete mineralization, as observed for zeolite Y. It was unclear what unique feature of zeolite Y is promoting this process, since the zeolite is not directly involved in the electrochemistry.

Figure 35. Mechanism for Wacker oxidation of propene in pure water by dispersed Pd(II)- and Cu(II)-modified zeolite Y.

3.3.2 Mesoporous Materials

Mesoporous materials extend the range of porosity to 500 Å, although most studies have been done with materials in the range 20–100 Å. The availability of the larger pores and control of the pore size within a narrow range made it possible to use mesoporous materials as hosts for reactions with molecules of varying sizes. Redox chemistry using metal-substituted frameworks, metallic oxides, entrapped complexes and enzymes has been reported. The major difference with zeolites is that the use of both larger substrates (that can readily penetrate the mesoporous framework) and grafting of larger catalytically active metal complexes has become possible. Several review articles summarize the research in this area [177].

Framework involvement

As we discussed in the section on zeolites, titanium-substituted zeolitic structures show very high catalytic activity and selectivity in oxidation reactions. Immediately after the report of the synthesis of MCM-41, it was realized that incorporation of Ti would make it possible to examine the oxidation of bulkier substrate molecules and to use larger oxidants. Indeed, Ti-MCM-41 showed higher catalytic activity for the epoxidation of norbornene with TBHP as the oxidant as compared with Ti-ZSM5 and Ti-zeolite β [178]. 2,6-Di-*tert*-butylphenol (2,6-DTBP) was oxidized to the quinone using H_2O_2 [179]. Vanadium-incorporated MCM-41 has also been found to be active for the partial oxidation of cyclododecane and 1-naphthol using H_2O_2 as the oxidant [180]. Interesting differences in catalytic activity have been noted for Ti-mesoporous materials made by different routes. For example, Ti-HMS (hexag-

onal mesoporous silicas) prepared by a neutral surfactant exhibited greater catalytic activity than Ti-MCM-41 for the oxidation of aniline [181]. Zr-HMS exhibited similar activity to the Ti analog and in both cases the turnover numbers were 10–50 times higher than with Ti-silicalite. Ti-MCM-41 incorporated into polymethoxysilane films was used for the epoxidation of *cis*-cyclooctene with TBHP as the oxidant [182]. Other organic reactions that have been reported with Ti-mesoporous materials include the oxidation of sulfides to sulfoxides and sulfones [183].

Few redox studies with cubic mesoporous materials have been reported [52]. The large, complex, three-dimensional pore system offers a unique environment. Ti- and Cr-substituted MCM-48 have been studied for the selective oxidation of methyl methacrylate and styrene to methyl pyruvate and benzaldehyde, respectively, using peroxides as oxidants and were found to outperform TS-1. Ti-MCM-48 has also been found to be better than Ti-MCM-41, TS-1 and TiO₂ for the photocatalytic reduction of CO₂ and H₂O to methane and methanol. Ti-grafted MCM-48 has also been reported as the first functional biomimic of vanadium bromoperoxidase, active at neutral pH and used in the peroxidative halogenation of bulky organic dyes.

Even though the metal-substituted, mesoporous solids allow the oxidation of molecules that is not possible with zeolites, there are several issues that still need to be addressed. First, the activity of the metal-loaded catalysts decreases with increased metal loading, e.g. for Ti-MCM-41, the peak activity for alkene epoxidation is attained at 2 wt. % [44a]. Second, metal leaching can occur and care needs to be exercised in concluding that oxidation is taking place at the framework site rather than via metal ions leached into solution [184, 185]. Leaching has been shown to occur for V-substituted mesoporous materials in the oxidation of alkanes [184]. X-ray absorption spectroscopy indicates that the inclination of the heteroatoms to remain in the MCM-41 framework after calcination follow the order Ti > Fe > V > Cr [56].

Few studies have also been reported with metal oxide clusters in mesoporous materials. MCM-41 modified by deposition of vanadium and titanium oxides exhibited catalytic activity for reduction of nitrogen oxides by NH₃ [186].

Entrapped species

Several routes to incorporating transition metal complexes in mesoporous materials have been reported. As in zeolites, Al incorporation in MCM-41 generates ion-exchange sites and has been used to introduce charged complexes into mesoporous materials. An example is phenanthroline iron(II) chloride, which was used as a catalyst for the oxidation of phenol with H₂O₂ [187]. Enhancement of activity was observed due to immobilization, but there were problems with leaching of the complex. Several strategies have been developed for chemically linking organometallic complexes on the inner walls of MCM-41, which alleviates leaching of the complexes during subsequent reactions. The anchoring methods have exploited the presence of silanol groups lining the pores. Titanium has been incorporated in MCM-41 by grafting of titanocene to triethylamine-activated silanol groups [188]. Upon calcination, the titanium was found to be tetrahedrally coordinated via the silanol groups and was a selective catalyst for the epoxidation of cyclohexene and

Figure 36. Schiff base ligands that have been covalently bound to MCM-41 framework.

pinene using TBHP as oxidant. The catalysts deactivated with 90 min of reaction, but could be regenerated by calcination.

Another strategy has been to condense the pore-lined OH groups of MCM-41 with a trialkoxysilane derivative to generate a stable $\text{O}_3\text{Si}-\text{R}$ linkage. The R group can then be modified with appropriate reactants to form a ligand. For example, Schiff base ligands have been formed by reacting MCM-41 with $(\text{CH}_3\text{O})_3\text{Si}(\text{CH}_2)_3\text{Cl}$, which generated $-\text{O}_3\text{Si}(\text{CH}_2)_3\text{Cl}$ groups bound to the MCM-41 framework. Treatment of the derivatized MCM-41 with ligands shown in Figure 36 led to bonding of the ligand at the R' site with the 3-chloropropylsilane moiety. The Schiff base ligands were then treated with an Mn^{2+} salt followed by oxidation to form the Mn^{3+} epoxidation catalyst [189]. Mesoporous silicas appear to possess patches of hydrophobic clusters made up of siloxanes and non-H-bonded silanol groups. The hydrophobic nature of the patches insures that the anchoring chloroalkylsilane chains migrate to these sites. For the parent mesoporous material the surface area and mesoporous volume were $947 \text{ m}^2 \text{ g}^{-1}$ and 0.72 mL g^{-1} , respectively, whereas for the $\text{Mn(III)}-\text{tSalpr}$ derivatized material these values were $672 \text{ m}^2 \text{ g}^{-1}$ and 0.41 mL g^{-1} respectively. The ligand grafting led to a decrease in surface area and mesoporous volume. However, as Figure 37 shows, the adsorption and desorption isotherms (type IV) were characteristic of the starting material, indicating that the textural properties were preserved. These complexes were examined as catalysts for styrene oxidation using PhIO as oxidant. For the $\text{Mn(III)}-\text{Salpr}$ and $\text{Mn(III)}-\text{tSalpr}$ complexes, the selectivity for epoxide formation was 58 and 24 %, respectively. The relatively low selectivity compared with unsupported complexes was explained as being due to the formation of by-products that were absorbed on the catalyst surface [177a].

Ru -porphyrin complexes covalently bound to MCM-41 were used as catalysts for the oxidation of alkenes, giving turnover numbers 20–40 times higher than the free complex [190]. Porphyrin complexes have also been attached to Nb dopants in the MCM-41 matrix, and behaved as cyclohexene epoxidation catalysts and were stable towards ligand degradation [44b]. Grafting of ethylenediamine ligands on

Figure 37. Nitrogen adsorption-desorption isotherms of parent mesoporous material MTS (solid line), Cl-MTS (dashed line) and tSalpr-MTS (dotted line). MTS = micelle templated silica, Cl-MTS = MTS modified by 3-chloropropylsilane and tSalpr-MTS = MTS modified with Mn(III) *N,N'*-bis[3-(3,5-di-*tert*-butylsalicylideneamino)propyl]amine.

walls of MCM-41 followed by complexation of Co(II) gave rise to the formation of a reversible dioxygen adduct [191]. The H_2O_2 -resistant ligand tmtacu (triamine-1,4,7-trimethyl-1,4,7-triazacyclononane) has also been grafted on mesoporous silicas and was found to be an excellent catalyst for styrene and cyclohexane epoxidation in the presence of Mn^{2+} and H_2O_2 [192].

Thus, mesoporous structures, because of their pores, make it possible to incorporate large catalytically active transition metal complexes. Covalently grafting these complexes in the hydrophobic patches provides better dispersion of the catalyst, as well as resistance to leaching. Improvement in catalytic performance is to be expected when materials with even larger pore diameters are studied. It will also be necessary to passivate the silanol groups responsible for promoting adsorption on the catalytic surface.

The large size of the pores of MCM-41 has also allowed the entrapment of enzymes, such as cytochrome *c*, papain and trypsin [193]. Enzyme entrapment has been extensively performed with sol-gel materials. The types of applications of redox catalysis using enzyme-mesoporous materials is expected to parallel the sol-gel materials, which is discussed in the last section of this chapter.

Electrochemistry

Electrochemical studies with mesoporous materials are only beginning to be explored [194]. Electroactive species can be introduced via ion exchange or by covalently attaching species in the mesopores. Balkus and co-workers were the first to examine the electrochemistry of anchored amine-ligated Co^{2+} complexes [191].

In particular, framework-bound ligands such as ethylenediamine (ED), diethylenetriamine (DET) and ethylenediaminetriacetic (EDT) acids were examined. Cobalt(II) complexes were formed by exposing the amine-derivatized MCM-41 to CoCl_2 solution. Working electrodes were made by pressing an MCM-41-graphite mixture on to a platinum grid, similar to the procedures used for making ZME. Electroactivity as measured by cyclic voltammetry (CV) was only observed if free uncomplexed ethylenediamine (en) ligand was present in the solution. The potential of the reversible redox couple was observed at -0.62 V vs. SCE and was similar to that of Co(en)_3^{2+} in solution. However, since the peak intensity did not decrease with time, it was proposed that the electroactive cobalt complexes were still grafted on to MCM-41. The excess en in solution was necessary to form mixed-ligand complexes (en, ED), (en, EDT), (en, DET) prior to observation of electrochemical activity. The CV signals observed corresponded to only a small fraction of the total cobalt in the MCM-41, indicative of electrochemical activity of only surface bound species.

Villemure and Pinnavaia examined the redox activity of Ru(bpy)_3^{2+} adsorbed or exchanged in mesoporous HMS and Al-HMS [195]. The electrochemical activities of the Ru(bpy)_3^{2+} ions that diffused out of the support were analyzed by CV. Walcarius and co-workers developed electroanalytical methods using MCM-41 [196]. The MCM-41-carbon paste electrode was found to be a good and selective preconcentrating medium for Cu^{2+} and Hg^{2+} in the presence of NH_3 . The preconcentration of millimolar levels of Cu^{2+} and Hg^{2+} was possible in the presence of a 1000-fold excess of alkali and alkaline earth metal cations and a 10-fold excess of other transition metal ions. After preconcentration, the analytes were exchanged out in a strongly acidic medium and analyzed by CV. In the case of mercury(II), the high discrimination against other cations was attributed to the fact that between pH 4 and 7, Hg(OH)_2 is the main soluble species and it can condense with the silanol groups of MCM-41, whereas other ions not in the hydroxide form cannot react with the silanol groups [197].

3.3.3 Sol-Gel Materials

Prior to the early 1980s there was minimal research on the incorporation of organic or biological compounds within ceramic materials [198]. Typical manipulation of ceramics occurs over 1000°C , well beyond the survival threshold for any biological or organic compound. However, sol-gel chemistry has altered this field since it lends itself well to the entrapment of chemically interesting species. The larger pores of sol-gel materials as compared with zeolites and MCM-41 type of materials have led to the encapsulation of many enzymatic systems. The entrapment of molecules is usually done by one of two methods: direct physical entrapment or by functional modification of the inorganic matrix by copolymerization with organo-metal alkoxides, and is represented schematically in Figure 38 [63i]. Direct doping of the sol-gel system is the easiest and most straightforward. In this procedure the dopant is added to the polymerizing mixture and, upon completion of the polycondensation, is entrapped within the inorganic polymeric network. Research on sol-gel-entrapped organic species has led to the realization of several general traits [199]. Most mole-

Figure 38. Schematic comparison of the entrapment procedures for sol-gel materials: (a) direct doping and (b) functional modification by copolymerization with organo-metal alkoxides.

cules can be entrapped within sol-gel matrices. Once entrapped, the dopant retains most of its physical and chemical properties. The pore network of the sol-gel permits the access of external reagents, allowing for chemical reactions and interactions. Materials made from sol-gel materials are optically transparent into the UV range, allowing for photochemical studies. Hydrocarbon oxidation using Ti-containing silicas has the potential to rival the studies done with mesoporous materials and, coupled with the fact that silica synthesis does not require templating agents, the possibilities are intriguing. Sol-gel techniques have led to materials with a high density of Ti-O-Si centers and 20 wt. % of titania with epoxidation catalytic activity poorer than 2 wt. % titania-MCM-41, but larger conversions than MCM-41, presumably because of the larger content of titanium [200].

Photochemical ET reactions

The photochemical inertness of the silica sol-gel makes it a good host for photochemical ET reactions. The porous architecture has been exploited to extend the lifetimes of charge-separated species [201]. For the system

where Py* is photoexcited pyrene and MV²⁺ is the methylviologen cation, Py⁺ and

Figure 39. Changes in absorbance with respect to time for Py^+ (446 nm, \circ) and MV^+ (610 nm, \bullet) after irradiation of Py (4×10^{-5} M), DQ^{2+} (5×10^{-4} M), MV^{2+} (3×10^{-6} M) sol-gel system.

$\text{MV}^{+\bullet}$ are formed transiently and disappear quickly because of the back ET reaction. However, when the pyrene and methylviologen are entrapped within a silica sol-gel network in the presence of the mobile charge carrier N,N' -tetramethylene-2,2'-bipyridinium (4-DQ^{2+}), photoexcitation leads to the creation of long-lived $\text{MV}^{+\bullet}$ [201a]. This is because the 4-DQ^{2+} acts as a shuttle between the Py^* and MV^{2+} :

The photogenerated $\text{MV}^{+\bullet}$ and Py^+ can be monitored at 610 and 446 nm, respectively. As Figure 39 shows that, upon photolysis, the signal due to Py^+ decreases, whereas that due to $\text{MV}^{+\bullet}$ increases with time. At $[\text{MV}^{2+}] = 3 \times 10^{-6}$ M, the photogenerated redox species lasts up to 4 h and consists of $\sim 5\%$ of the radicals initially formed [201a].

Another important example of a photochemical ET reaction in a sol-gel is the reduction of H_2O to H_2 [201]. The donor $[\text{Ru}(\text{bpy})_3]^{2+}$ and acceptor $\{\text{Ir}(\text{bpy})_2[(\text{C},\text{N}')\text{bpy}]^{3+}\}$ were both entrapped in the sol-gel and dimethoxybenzene (DMB) was used to transport the charge between them. The following reactions were proposed for generation of H_2 :

After several thousand laser pulses at 390 nm, H₂ was detected using gas chromatography. H₂ was produced with a quantum yield of ~1 % and it was estimated that the turnover number for Ir(III) as a catalyst for H₂ generation was >100.

Enzymatic redox reactions

The redox chemistry of enzymes encapsulated within sol–gels has been an area of extensive research [198]. Initially, there was no reason to believe that enzymes would remain active upon sol–gel encapsulation. The enzyme could react with the alkoxide and be destroyed either by the pressure of matrix shrinkage or the release of toxic alcohols during the hydrolysis. In contrast to these expectations, it has been found that enzymes such as trypsin, which completely digests itself in solution, retains full activity for months upon sol–gel incorporation [202]. Other enzymes also show an increase in stability upon sol–gel entrapment [203]. Acid phosphatase experienced an increase of two orders of magnitude in its half-life, increasing from 0.1 min in solution to 12 min upon entrapment [203b]. The increase in stability can be attributed to the spatial restrictions placed upon the entrapped enzyme. The rigid structure of the sol–gel matrix may interfere with the unfolding of the enzyme associated with denaturation.

One of the most widely studied enzymes in sol–gels has been glucose oxidase on silica [202, 204]. Shtelzer and Braun developed a reversible optical glucose sensor based on the loss of color of the isoalloxazine moiety of the enzyme upon reductive complexation of glucose [204a]. The sol–gel/glucose oxidase system has also been used as a diagnostic tool. Hydrogen peroxide, a reaction product of glucose oxidase, was monitored via a second enzymatic reaction (peroxidase-based) with aromatic aza compounds [204]. The products of this reaction are colored and easily monitored spectroscopically. This system demonstrates the ability of the sol–gel matrix to play host to several working enzymes.

Enzyme encapsulation along with photochemical electron transfer within the sol–gel network has been studied by Shen and Kostic [205]. The enzyme zinc cytochrome *c* (Zncyt) has a long-lived triplet state that can be oxidatively quenched. Zncyt was entrapped in the sol–gel during the synthesis stage and the quencher, either [Ru(NH₃)₆]³⁺ or [Ru(NH₃)₅Cl]²⁺, was introduced by soaking the preformed sol–gel/enzyme system in a 2×10^{-4} M quencher solution [205a]. The ruthenium complex preferentially collected within the pore system and quenched the excited state of the enzyme. Figure 40 shows the decay of the transient absorption of ³Zncyt with and without quencher [205]. The upper decay corresponds to unquenched ³Zncyt and was fitted to a rate constant of 70 ± 10 s⁻¹. The lower decay is ³Zncyt upon quenching with [Ru(NH₃)₆]³⁺ and was fitted to three rate constants of 100, 570 and 3900 s⁻¹. The single exponential decay in the absence of quencher indicates a similar environment for all proteins, whereas the different decays upon quenching are indicative of a microheterogeneous media.

Another study involved native cytochrome *c* (iron containing) and the quenchers [Fe(CN)₆]³⁻, dioxygen and *p*-benzoquinone. The influences of ionic strength and pH on the quenching abilities of these molecules in solution were investigated [205b]. It was found that the assumption of uniform dispersion of small species

Figure 40. Transient absorbance (460 nm) of the triplet state of Zncyt ($^3\text{Zncyt}$) encapsulated in a sol-gel glass. Upper trace is in the absence of a quencher, lower trace in the presence of $[\text{Ru}(\text{NH}_3)_6]^{3+}$.

within sol-gel networks is not necessarily true and should be tested for each substrate.

Electrochemistry

Sol-gel systems provide several advantages in the design of electrochemical systems. They have favorable abrasion resistance, good optical characteristics and the ability to tailor the hydrophobicity and affinity of molecules towards the network. Leaching of active species from within the network is a problem and several methods are available to avoid or minimize this event [206]. The reagent of interest can be covalently bonded to the framework [207]. This eliminates all leaching, but requires the use of organic synthesis in the preparation and is usually accompanied by a change in the formal potential. Bulky dopants such as polymers can be used and will eliminate mobility of the encapsulated reagent, but also requires more in-depth synthesis schemes [208]. These two methods can only be used in situations where there is no requirement for the movement of the dopant. The sol-gel can also be modified to increase its affinity for the encapsulated species [198]. This is done by using organically modified sol-gels to tailor the degree of hydrophobicity to suit the encapsulated species. These systems tend to be easier to prepare and have less of an effect on the formal potential, but will also result in an eventual leaching of the reagent.

Electrochemistry has been used to study the effect of sol-gel entrapment on redox agents. Collinson and coworkers selected six redox probes based on size, shape and charge and investigated their entrapment, activity and stability [209]. It was determined that the sol-gel network is a dense, collapsed system that prohibits the majority of the probes from being able to move to the electrode and exchange electrons. Anionic probes were found to be more stable in the sol-gel, which was attributed to the diffusion of cationic and neutral species out of the sol-gel and into the solution. It was unclear as to why the anionic probes showed increased stability,

Figure 41. Square-wave voltammograms for 1.0 mM $\text{Fe}(\text{CN})_6^{4-}$, 0.1 M KCl at (1) a bare graphite electrode, (2) a sol-gel-modified electrode and (3) a sol-gel-PDMAAC-modified electrode after a 10 min exposure time.

especially considering that the sol-gel itself should be negatively charged. Two hypotheses were presented. The first was that the driving force to retain the probes was higher than the electrostatic repulsion and the second attributed the result to a concentration phenomenon. However, neither of these could be proven.

Sol-gels containing electroactive species have been used in the development of both amperometric and potentiometric electrodes. Films coated with anionic poly-(dimethyldiallylammonium chloride) (PDMDAAC) and cationic poly(vinylsulfonic acid) were used to concentrate $\text{Ru}(\text{bpy})_3^{2+}$ and the hexacyanoferrate anion, respectively, for use as amperometric electrodes [208a]. The detection limit by square-wave voltammetry improved by up to 50-fold compared with uncovered electrodes. In Figure 41, curve 1 corresponds to a bare graphite electrode, curve 2 to a sol-gel-covered electrode and curve 3 to a sol-gel-PDMDAAC-modified electrode after 10 min of exposure to $\text{Fe}(\text{CN})_6^{4-}$.

Ion-selective membranes have been developed using the carrier valinomycin and a 12-crown-4 derivative for the detection of potassium and sodium ions. Leaching was originally a problem, but was later avoided by using covalently bonded reagents [207, 210].

Several electrochemical studies have focused on the glucose oxidase system for sensor applications. Tatsu and co-workers reported an electrochemical oxygen sensor coupled to a sol-gel containing glucose oxidase using a nylon net and a cellulose membrane [211a]. The loss of oxygen from solution can be correlated with the glucose concentration, resulting in a glucose sensor. Figure 42 shows the response of the sensor to a series of glucose concentrations and a calibration curve [211a].

Figure 42. Output current of a sol-gel-entrapped glucose oxidase electrochemical sensor. Standard solutions of 0, 25, 50, 100, 200 and 400 mg dL^{-1} of glucose were injected over 20 min periods. Inset shows integrated peak area (charge) versus glucose concentration.

The response of the sensor peaked within 4 min and the calibration curve is applicable within the range of glucose concentrations in normal human serum. Another glucose sensor using sol-gel systems was based upon glucose oxidase in conjunction with a mediator compound (ferrocene or hexacyanoferrate) that transferred an electron to the enzyme [211]. This system can be represented as

where E and EH_2 are the oxidized and reduced form of the enzyme, Q and P are the oxidized and reduced form of the mediator, G is the substrate (glucose), GL is gluconolactone, and EG is the complex formed between the oxidized enzyme and the glucose [211b]. The mediator, P, can then be reoxidized to Q at the electrode surface. This results in a Faradaic current proportional to the glucose concentration that is completely independent of oxygen.

Horseradish peroxidase (HRP) has also been used in sol-gel electrochemical systems. In the presence of a mediator [hexacyanoferrate(II) or ferrocene], sol-gel-entrapped HRP was used as a peroxide sensor [212]. Chuit et al. used this system in a sandwich configuration to achieve good sensitivity [213].

In a departure from SiO_2 -based sol-gels, an amperometric biosensor was developed by Glezer and Lev [214]. Sol-gels of V_2O_5 doped with V^{4+} provide good

electrical conductivity and adhere well to conductive supports such as platinum. When glucose oxidase is entrapped within this system the hydrogen peroxide produced as a result of glucose oxidation is oxidized at the metal support, resulting in the analytical signal.

Another example of a nonsilicate biosensor was developed by Milagres and co-workers [215]. Silica gel was coated with TiO_2 using a sol-gel method. Ferrocene, carboxylic acid and glucose oxidase were then adsorbed on the surface. Large loadings of the enzyme were possible owing to the large surface area of the powder. The voltammogram response was found to be affected by the nature of the supporting anion, which caused a shift in midpoint potential. The sensor was tested by measuring glucose in blood serum and resulted in a correlation coefficient of 0.9996.

Lev and co-workers developed the composite carbon-silicate electrode (CCE) [216]. In these electrodes, the silica sol-gel is mixed with graphite or carbon black powder. At a critical concentration of carbon within the sol-gel (beyond the percolation threshold), there becomes a continuous path(s) of conductive carbon throughout the system. The sol-gel system used was a methyl silicate network (by using methyltrimethoxysilane as the sol-gel precursor, the resulting network has exposed SiCH_3 groups), which imparts hydrophobic properties to the electrode [217]. This prevents water penetration and only the exterior of the electrode is exposed to electrolytes. When used with 30 nm sized carbon black powder, the conductive area of the electrode in contact with the electrolyte consists of less than 1 % of the geometric cross-sectional area of the electrode. This has been compared with an ensemble of microelectrodes. These CCEs showed an improvement of up to three orders of magnitude in terms of Faradaic signal-to-noise compared with glassy carbon electrodes [218]. In addition, the sol-gel method of preparation affords a variety of structural configurations and it has been shown that CCEs can be produced by thick film and ink jet technology, which allows for their mass production [219].

In order to improve upon the poor electrocatalytic activity of graphite, trace amounts of metal or organometallic catalysts were added. This was done in several ways. The organometallic catalyst can be placed within the graphite powder prior to the addition to the sol-gel precursors, or added separately to the carbon/sol-gel precursor mixture [217, 219]. CCEs containing the catalysts cobalt phthalocyanine and cobalt porphyrin showed good activity toward the electrocatalytic reduction of molecular oxygen. This property has been demonstrated with the reduction of carbon monoxide and oxidation of sulfur dioxide. Owing to the porosity of the sol-gel network, these CCEs can be used as electrical sensors in the gas phase. Using these electrodes, a gas-phase oxygen sensor with a 0.8 s response time (90 % signal change) with a linear range of 0–0.21 atm was fabricated.

CCEs have also been used in conjunction with enzymes. Glucose oxidase was encapsulated within the methyl silicate (or silica)-graphite composite [216, 220]. Reduced oxygen from the enzymatic reaction results in the production of H_2O_2 , which is oxidized at the electrode. Palladium and rhodium catalysts have been added to the electrode to help lower the over voltage required for hydrogen peroxide oxidation [219, 221]. Glucose oxidase and horseradish peroxidase have been simultaneously entrapped within a CCE for a biosensor that does not require a

Figure 43. Response of 400 mV (vs. SCE) polarized TTF-mediated glucose oxidase-modified CCE upon sequential additions of 2.5 mM glucose solutions. Insets show details of response at the indicated times.

mediator [222]. The enzymatically generated H_2O_2 was detected at a potential of 0 V (vs. SCE), limiting the influence of interfering species. The performance was optimized by using two separate CCEs, each containing one enzyme, configured into a bilayer structure.

To improve further the characteristics of these systems, the use of mediators (either entrapped or chemically attached to the silicate network) has been investigated [220, 221]. Tetrathiafulvalene was used as a mediator with the glucose oxidase system to allow for oxygen-independent measurements. The performance of this sensor is shown in Figure 43 [220]. The electrode has a response time of 30–100 s upon addition of 2.5 mM glucose solution. The longer response times at higher concentrations are due to a lower reaction order. In another variation, ferrocenyl groups were covalently attached to the glucose oxidase itself before incorporation within the sol–gel [223].

The CCE–glucose oxidase system has evolved even further with the direct wiring of the enzyme [225]. The system consists of graphite powder and glucose oxidase in a ferrocene-, amine- and methyl-modified silicate sol–gel network. In the final electrode, each part makes its own contribution to the system. The silicate network provides the porous support, the graphite provides the conductivity, ferrocene provides the transduction of the signal from enzyme to the conductive surface, amino groups effect the anchoring of the enzyme to the surface via attraction to the negative charges of the enzyme surface and the methyl and amino groups provide the hydrophobicity to control the wetted area of the electrode.

Ruthenium-dispersed sol–gel thick-film electrodes were developed by Wang and co-workers [219]. All of these systems showed shelf-life stability in excess of 4 months and excellent selectivity over common interferents such as ascorbic acid, acetaminophen and uric acid. Based on this work, electrodes for lactate and amino

acid sensing were prepared using lactate oxidase and amino acid oxidase, respectively [224].

Bharathi and Lev developed a gold–ceramic composite and used it for glucose sensing [226]. This system is similar to CCEs with the graphite powder replaced by gold nanoparticles. In this system, the gold provides both the conductivity and the electrocatalytic activity required.

3.4 Conclusions

We have discussed in some detail ET reactions occurring in zeolites, mesoporous materials and sol–gels. The unifying theme across these three different types of materials is their porosity. ET reactions within the pores with molecules as small as propylene to complex enzymes such as glucose oxidase have been discussed. However, what is also apparent from the discussions are that each host matrix imposes its own unique characteristics on the reactions within its pores. We conclude by highlighting the uniqueness of each matrix.

Zeolites are microporous frameworks, and all of the ET chemistry that we have discussed is with molecules smaller than 13 Å. The unique features of zeolites are their ion-exchanging ability, a stable structure upon dehydration and a pore/channel structure that allows for a well-defined arrangement of molecules in space and the fact that redox-active atoms can be substituted on the framework. In most cases, the zeolite is an active host, influencing ET reactions via electrostatic fields or steric effects, a feature that is not found with the mesoporous and sol–gel materials. Packing of molecules/ions in the intrazeolitic space with very high densities is also possible and was found to be important in charge propagation and electrochemistry.

Mesoporous materials extend the range of porosities to the tens of ångströms scale. Although this provides a major advantage due to the increase in size of the molecules that can be introduced into the pores, several advantages of zeolitic-like systems are lost in the translation. The most important factor is that the framework of the mesoporous materials is amorphous. Thus, strong acidity and specific siting of redox active atoms on particular crystallographic sites are not possible. Increases in the size of the pores and the siliceous nature of the framework also limit the electrostatic effects that have been extensively exploited with zeolites. On the other hand, the silanol groups in the framework of mesoporous materials have found extensive use in anchoring of complexes. The ion-exchange properties of Al-doped mesoporous materials have not been exploited as yet. The major impact of mesoporous materials on ET reactions has been the study of the redox chemistry of larger substrates with metals doped into the framework. In the case of hydrocarbon oxidation, mesoporous materials have clearly broadened the scope of applications.

Sol–gel materials have found most promise in exploiting enzyme-based redox chemistry. The larger porosity and the very simple methods of entrapment have facilitated the use of enzyme–sol–gel systems. Lack of a regular pore structure makes the architecture of molecular assemblies difficult with sol–gel materials,

especially compared with zeolites. Attempts are being made to use doped sol-gel materials as redox catalysts, and could be in competition with mesoporous materials. However, issues regarding the use of H_2O_2 as oxidant, the long-term leaching of redox-active atoms and the regeneration of the catalyst by calcination need to be resolved if sol-gel materials are going to be important in hydrocarbon redox reactions.

Summarizing the field of ET using porous materials, it appears that zeolites act as active hosts and have advantages of manipulating reaction rates and product yields involving small molecules due to the close fits of the size of the molecule and cages. Mesoporous materials make it possible to examine the redox chemistry of larger molecules as compared with zeolites, while sol-gel materials form the primary hosts for enzyme-based redox reactions.

4 Electron Transfer in Layered and Intercalated Compounds

Vasudeva Bhat and Kazunari Domen

4.1 Introduction

Layered compounds provide unique character for electron-transfer processes owing to their low dimensionality. Especially layered materials with ion-exchange and/or intercalation capabilities show behavior that is not seen in so-called bulk-type materials. Layered materials, which have been often used in studies of photoelectron transfer as well as photocatalysis, may be classified into two groups: compounds in which the host layers work as an active component for the photoexcitation and electron-transfer reactions, and materials in which the layers are inert for electron-transfer processes. Examples of the former are layered titanates and niobates and of the latter are clays. In the latter case, photoactive materials are intercalated in the interlayer spaces. Recently, the exfoliation of various layered compounds has become possible and artificial assemblies consisting of these exfoliated sheets have been formed. Electron transfer in such assemblies is also an attractive subject in this field.

4.2 Layered Oxides of Transition Metals

Transition metal elements such as Ti, Nb and Ta, which form d^0 cations, are known to form several oxides with layered structure exhibiting interlamellar activity. Figures 1 and 2 show the idealized structures of some of these oxides.

All of these oxides consist of titanate and/or niobate macropolyanion sheets and alkali metal cations in between to compensate the negative charges of the sheets. The alkali metal cations can be replaced by various kinds of cations, including protons. These oxides may be regarded as semiconductors/insulators owing to their large band-gap. The electronic state of the oxide sheets is excited when the photons with the energy larger than the band-gap (typically in the ultraviolet region) are

Figure 1. Idealized structures of some layered titanates and titanoniobates possessing edge- and corner-connected octahedra. Adapted from Refs. [1] and [2].

absorbed. This process may be regarded as the excitation of electrons from the valence band, mainly consisting of O 2p orbitals, to the conduction band, mainly consisting of Ti or Nb 3d orbitals. Based on the band models of the electronic states, the excitation process is depicted as the formation of electrons (e^-) in the conduction band and positive holes (h^+) in valence band. If electrons and holes are localized, they may be regarded as Ti^{3+} or Nb^{4+} and O^- species. The detailed dynamic behavior of these excited states has not been fully revealed. Judging from the results of photocatalytic reactions, the behavior of photoexcited electrons and holes seems to be more or less similar to that of bulk-type titanates and niobates. In principle, however, these photoexcited electrons and holes should be regarded as being confined in two-dimensional sheets of the oxides.

Figure 2. Idealized structures of some perovskite-related layered oxides and their fluoride relatives. Fluoride structures adapted from Ref. [3].

Among these oxides, $\text{K}_4\text{Nb}_6\text{O}_{17}$ has been studied in some detail, although the structure is rather unique. Hence studies on this oxide will be introduced first, followed by those on other layered oxides. Tables 1 and 2 list various systems studied for photocatalysis.

4.2.1 $\text{K}_4\text{Nb}_6\text{O}_{17}$

Structure and physico-chemical properties

Single crystals of $\text{K}_4\text{Nb}_6\text{O}_{17}$ can be obtained by slow cooling of the melt near 1200°C [4, 34, 35]. Powder samples can be prepared by conventional ceramic methods at about 1100°C . X-ray powder patterns have been reported [4]. The BET

Composition	Unit cell dimensions	No. of H_2O of hydration	Estimated band-gap/absorption edge	Estimated conduction band edge/V vs. NHE
$\text{K}_4\text{Nb}_6\text{O}_{17}$	Orthorhombic, $a = 0.758$, $b = 3.23$, $c = 0.640$ nm [4], $a = 0.783$, $b = 3.32$, $c = 0.646$ nm [5]	0, 3 and 4.5 [4]; 3 [5]	3.52 eV [6], 3.3 eV [7], 360 nm [8]	-0.76 [6]
$\text{Rb}_4\text{Nb}_6\text{O}_{17}$	Orthorhombic, $a = 0.779$, $b = 3.319$, $c = 0.650$ nm [5]	3 [5, 9]	360 nm [8]	
$\text{Rb}_4\text{Ta}_6\text{O}_{17}$	Orthorhombic, $b = 3.45$ nm [8]	~ 3 [8]	295 nm [8], 4.4 eV [10]	
$\text{A}_4\text{Ta}_x\text{Nb}_{6-x}\text{O}_{17}$ (A = K, Rb; $x = 2, 3, 4, 6$)	Orthorhombic, $b = 3.32\text{--}3.45$ nm [8]		295–410 nm [8]	
$\text{K}_2\text{H}_2\text{Nb}_6\text{O}_{17}$			3.45 eV [6]	-0.265 [6]

surface area of the ceramic preparation [11] is typically of the order of $1 \text{ m}^2 \text{ g}^{-1}$. Hydrothermal synthesis can be used to prepare the single-phase oxide at temperatures as low as 280°C with four times the surface area [36]. Catalytic properties of such preparations have not been examined.

This oxide has a layered structure [5] consisting of $[\text{Nb}_6\text{O}_{17}]^{4-}$ macropolyanion sheets interleaved by K^+ ions, as shown in Figure 3. The K^+ ions can be replaced by various mono- and multivalent metal cations [12, 37, 38], protons [6, 12, 38, 39] and organic cations [40]. An important aspect of the structure is the presence of two types of interlayer regions [5, 9], referred to as interlayer-I and interlayer-II, with differing interlayer reactivities [37]. This makes the $[\text{Nb}_6\text{O}_{17}]^{4-}$ sheets non-symmetric with respect to mirror reflection about the sheet-planes. Besides the anhydrous compound of the above formula, it also forms two hydrates, one with about three water molecules of hydration, which is stable in the humidity range 25–85 %, and the other with about 4.5 molecules of water of hydration, which is stable above 85 % humidity [4]. These hydrates are structurally related to the anhydrous oxide: the H_2O molecules are accommodated in the interlayer-I together with the already existing K^+ ions, leaving the $[\text{Nb}_6\text{O}_{17}]^{4-}$ sheets and interlayer-II intact [5, 9]. The possible existence of higher hydrates being formed under aqueous environments has also been suggested [4]. Such spontaneous intercalation of water molecules is an important feature in making this oxide a photocatalyst, especially for water splitting.

$\text{K}_4\text{Nb}_6\text{O}_{17}$ crystals exhibit optical birefringence [34] and absorb in the UV region with an optical absorption edge between 320 and 330 nm. Figure 4 shows the wavelength dependences of the transmittance and absorption coefficient along the

Figure 3. Schematic structure of $\text{K}_4\text{Nb}_6\text{O}_{17}$. Adapted from Ref. [5].

b -axis of a $\text{K}_4\text{Nb}_6\text{O}_{17}$ single crystal [41]. Figure 5 shows the photoluminescence spectra taken at 77 K [42]. Kudo and Sakata have reported on the effect of ion exchange on the luminescence properties [38, 39]. Photoconductivity measurements on single crystals [43] (Figure 6) also reveal UV light-assisted conductivity in the a - c plane. A band-gap of 3.3–3.5 eV has been estimated from diffuse reflectance measurements on powder samples [7] and on samples suspended in aqueous media [6].

Electrical conductivity measurements [41] along the b -axis and in the a - c plane reveal an extreme anisotropy: $\sigma = 2.0 \times 10^{-16} \text{ S cm}^{-1}$ in the b -direction and $1.4 \times 10^{-12} \text{ S cm}^{-1}$ in the a - c plane. The measurements were carried out on single crystals after the currents had reached a steady value to avoid the effect of ionic

Figure 4. Transmittance and absorption spectra of single-crystal $\text{K}_4\text{Nb}_6\text{O}_{17}$ along b -axis. From Ref. [41].

conductivity. The applied voltages were 100 V/10 μm along the b -axis and 1 V/3 mm in the a - c plane.

Photocatalytic overall water splitting

In distilled water, $\text{K}_4\text{Nb}_6\text{O}_{17}$ without any modification evolves H_2 and O_2 under band-gap irradiation. This indicates that the photoexcited electrons and holes have enough potential to reduce and oxidize water. The rates of H_2 and O_2 evolution are,

^a Probable forms under experimental conditions.^b Rxxx–Oyyy: sample reduced at xxx K and then oxidized at yyy K.

however, very low. Various transition metal oxides have been used as promoters [14]. Table 3 gives the list of oxides used as promoters and the amount of hydrogen produced during water decomposition. As can be seen, NiO is found to be the best promoter.

Typically, Ni loading has been carried out as follows: the powdered $\text{K}_4\text{Nb}_6\text{O}_{17}$ is impregnated with dilute aqueous $\text{Ni}(\text{NO}_3)_2$ solution, evaporated to dryness with stirring and then calcined in air to decompose the nitrate to oxide. It is then subjected to evacuation and to activate the catalyst it is reduced in H_2 (at a pressure of about 40 kPa) at 500 °C for 2 h and then oxidized in O_2 (at a pressure of about 16 kPa) at 200 °C for 1 h. It is known that $\text{K}_4\text{Nb}_6\text{O}_{17}$, on treatment with NiCl_2 solution, exchanges the K^+ ions in interlayer-I with Ni^{2+} ions [37]. It was proved that a 0.1 wt.% loading of Ni with the above treatment procedure is the optimum condition for overall water splitting [7]. For such a sample, assuming 100 % exchange, less than 2 mol% of K^+ ions in interlayer-I are expected to be substituted. Figure 7 shows a typical time course of H_2 and O_2 evolution in distilled water for the optimally prepared catalyst. H_2 and O_2 are produced in a stoichiometric ratio and the total amounts of evolved H_2 and O_2 exceed that of catalyst. The quantum efficiency at 330 nm was estimated to be about 5 % [17] for the optimally loaded catalyst.

It should be noted that for $\text{K}_4\text{Nb}_6\text{O}_{17}$, irrespective of modification, the quantum efficiency reaches 20 % at 300 nm under low light intensities [41] (Figure 8). At higher light intensities, the rates of H_2 and O_2 evolution did not increase with light intensity; the dependence of the evolution rates on the light intensity was of the order of 0.52. This non-linearity at higher light intensity was attributed to the

Figure 7. Time course of H₂ and O₂ evolution over 0.1 wt.% Ni loaded K₄Nb₆O₁₇. From Ref. [14].

dominance of the recombination reaction of photogenerated electrons and holes over the redox reactions with water.

The pH of a suspension of Ni-loaded K₄Nb₆O₁₇ in water is about 11 and the suspension acts as a kind of buffer for addition of small amounts of acid or base. When a small quantity (about 0.05 wt.%) of KOH was added, the activity increased by about 30 % [17] but the pH remained unchanged. On changing the pH to lower or higher values by adding considerable amounts of acid or base, the catalytic activity decreased [7]. For example, the rate of water decomposition reduced to about half the value on changing the pH from 11 to 9 or to 13. Complete suppression of oxygen evolution was observed on addition of excess alkali to the reaction mixture, although the activity is regained on neutralizing the excess alkali with acid.

The substitution of K⁺ by Rb⁺ gives Rb₄Nb₆O₁₇, which was found to decompose water at twice the rate as the K⁺ analog [8].

Structure of Ni-loaded K₄Nb₆O₁₇ and the reaction mechanism

Ni-loaded catalysts have been characterized using various techniques such as XPS, EXAFS, ESR and TEM.

Figure 8. Quantum efficiency of $K_4Nb_6O_{17}$ samples as a function of power density of incident radiation. From Ref. [41].

XPS measurements demonstrated that loaded Ni predominantly locates between the layers of the catalyst and little remains on the external surface [15]. For sensitivity reasons, a sample with a 1 wt.% Ni loading was used. Comparison of the Ni $2p_{3/2}$ peak intensity in the catalyst with that in a reference sample (which was also 1 % Ni-loaded $KNbO_3$ with almost the same BET surface area as that of $K_4Nb_6O_{17}$) has shown that the surface concentration of Ni in the former is about 100 times less than that of the reference sample [7]. Table 4 presents the peak intensities normalized to Nb 3d peak intensities in these samples after various pretreatments.

EXAFS spectra for 1 wt.% Ni-loaded samples both before and after the reduction procedure, and also for Ni and NiO as standards, have also been examined [15], as shown in Figure 9. After reduction by H_2 at 500 °C for 2 h, the loaded Ni was completely reduced to the metallic state. Even after reoxidation by O_2 at 200 °C for 1 h, most of the Ni remained metallic. (By XPS, the Ni, which remained on the external surface, was found to be in the oxidized form.) The formation of metallic nickel on a 0.1 wt.% Ni-loaded catalyst was also confirmed by ESR measurements

Table 4. XPS peak intensity ratio of Ni $2p_{3/2}$ to Nb 3d [7].

Catalyst	Peak intensity ratio			
	Untreated	R773 ^a	R773–O473 ^a	R773–O773 ^a
NiO(1 wt.%)– $K_4Nb_6O_{17}$	0.026	0.004	0.004	0.05
NiO(1 wt.%)– $KNbO_3$	1.5	0.7	1.4	1.3
$NiNb_2O_6$	0.6			

^aR773: samples reduced at 773 K. R773–O473: samples reduced at 773 K and then oxidized at 473 K. R773–O773: samples reduced at 773 K and then oxidized at 773 K.

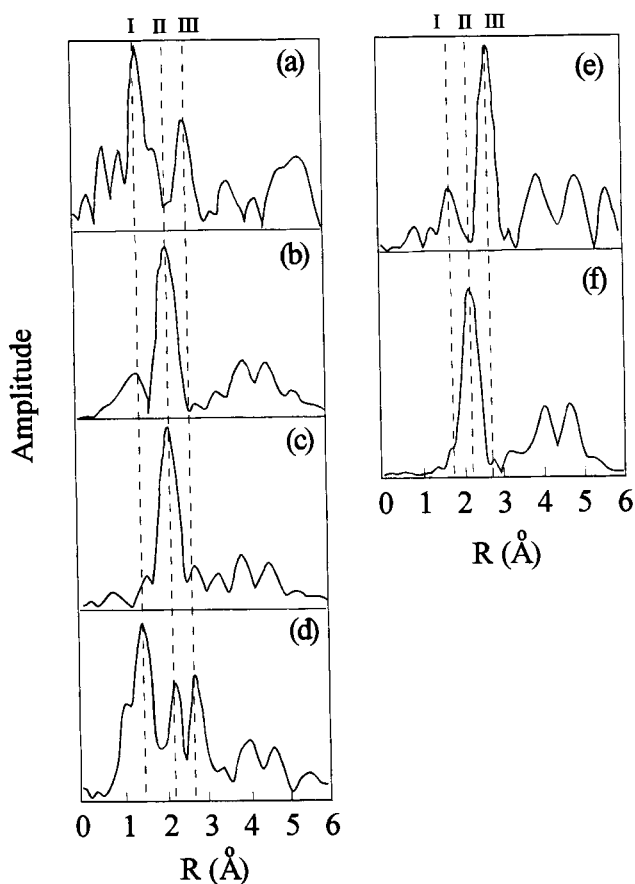

Figure 9. Fourier transforms of Ni K-edge EXAFS functions, $K^3X(K)$, of Ni (1 wt.%)– $K_4Nb_6O_{17}$ catalysts and reference samples. Phase shifts were not corrected. (a) Untreated; (b) reduced at 773 K; (c) reduced at 773 K and re-oxidized at 473 K; (d) reduced at 773 K and re-oxidized at 773 K; (e) NiO reference; (f) Ni metal reference. [7]. The appearance of an intense resonance line after the reduction and reoxidation indicates the formation of ferromagnetic metallic nickel in the sample.

TEM images of 0.1 % Ni-loaded samples showed the presence of ultra-fine particles of ca. 0.5–0.7 nm diameter, whereas for 1 % loaded samples, particles larger than 3 nm were also observed [15]. The rate of overall water splitting on the 0.1 wt.% Ni-loaded catalyst was twice that on the 1 wt.% Ni-loaded catalyst. Therefore, the Ni particles responsible for the enhancement of the activity are ultra-fine particles probably located at interlayer space-I. As mentioned above, XPS results indicated that these particles are present in the bulk of the catalyst. The larger particles observed in the 1 wt.% Ni-loaded sample are regarded as poisons because they exist in the bulk of the catalyst, leading possibly to destruction of the layered structure locally. X-ray powder diffraction did not show variations in d -spacing perpendicular to the $[Nb_6O_{17}]^{4-}$ sheets since the amount of Ni was very small.

Based on these characterizations, a model structure of 0.1 wt.% Ni-loaded $K_4Nb_6O_{17}$ was proposed as shown in Figure 10. During the loading of the catalyst with nickel, most of the nickel enters the interlayer region-I as Ni^{2+} by replacing K^+ ions, leaving a very small fraction on the external surface. During reduction at

Figure 10. Proposed mechanism of catalytic water decomposition by Ni-loaded $\text{K}_4\text{Nb}_6\text{O}_{17}$. Adapted from Ref. [15].

700°C , the Ni^{2+} cations are reduced to metallic nickel in the form of ultra-fine particles of about 0.5 nm size.

On the basis of this model, a possible reaction mechanism for overall water splitting on Ni-loaded $\text{K}_4\text{Nb}_6\text{O}_{17}$ has been proposed as follows.

On band-gap irradiation, electrons and holes are generated in the host lattice of $[\text{Nb}_6\text{O}_{17}]^{4-}$. The electrons are transferred to the nickel particles on which the hydrogen formation takes place. The holes migrate to the other side of the niobate sheet where water is oxidized to O_2 . Such separation across the sheet may be facilitated by an electrostatic gradient existing across the niobate sheets due to unequal K^+ environments on the two sides of the sheets. However, since the quantum efficiency of overall water splitting is at most 20 % as described above, such an electron-hole separation must not be so efficient. Most of the electrons and holes recombine within the host lattice. Probably some holes may react at interlayer-I with water molecules or Ni metal particles, which causes the reverse reactions or degradation of the activity. The degradation of the catalyst with continued use, as seen by the decreasing rate of production of gases with time (see Figure 7), has been attributed to the decreasing amount of metallic nickel in the sample. It should be noted that this reaction mechanism was inferred from the structure of the active catalyst, and has not been confirmed by any spectroscopic methods.

Modified $\text{K}_4\text{Nb}_6\text{O}_{17}$ systems

CdS and Ni- $\text{K}_4\text{Nb}_6\text{O}_{17}$ mixture

Hydrogen evolution reaction in aqueous K_2SO_3 solutions using physical mixtures of CdS and $\text{K}_4\text{Nb}_6\text{O}_{17}$ or Ni- $\text{K}_4\text{Nb}_6\text{O}_{17}$ powders has been studied [33]. In these

Figure 11. H_2 evolution under irradiation with visible light ($\lambda > 420$ nm) over several catalyst systems in aqueous K_2SO_3 solution (0.1 M, pH = 9.5, 250 mL): (a) $\text{CdS} + \text{NiO-K}_4\text{Nb}_6\text{O}_{17}$; (b) $\text{CdS} + \text{K}_4\text{Nb}_6\text{O}_{17}$; (c) CdS ; (d) $\text{NiO-K}_4\text{Nb}_6\text{O}_{17}$; (e) $\text{K}_4\text{Nb}_6\text{O}_{17}$. From Ref. [33].

experiments, light with $\lambda > 420$ nm was utilized. Figure 11 shows the time course of H_2 evolution using several catalytic systems. As can be seen, neither CdS nor $\text{Ni-K}_4\text{Nb}_6\text{O}_{17}$ is individually effective. On the other hand, a mixture of CdS and $\text{K}_4\text{Nb}_6\text{O}_{17}$ produces a considerable amount of H_2 gas. Ni -loaded $\text{K}_4\text{Nb}_6\text{O}_{17}$ showed much higher activity for H_2 generation. These results suggest that electrons excited in CdS by visible light are transferred to $\text{K}_4\text{Nb}_6\text{O}_{17}$. Furthermore, loaded Ni works as an H_2 evolution catalyst using electrons donated from CdS through the $[\text{Nb}_6\text{O}_{17}]^{4-}$ layer, because Ni exists as ultra-fine metal particles in the interlayer space as described in the preceding section. Optimization experiments have revealed that a mixture of 1 wt.% $\text{Ni-K}_4\text{Nb}_6\text{O}_{17}$ and CdS in a weight ratio of 1:1 at pH 10 is ideal for this system.

CdS-K₄Nb₆O₁₇

Under visible light irradiation, MV^{2+} (MV = methylviologen) was reduced in aqueous methanol in the presence of $\text{CdS-K}_4\text{Nb}_6\text{O}_{17}$ catalyst, even though CdS without niobate is ineffective under these conditions [27]. Here, the catalyst was prepared by partially (about 14 %) exchanging K^+ by Cd^{2+} in $\text{Cd}(\text{NO}_3)_2$ solution, followed by treatment with Na_2S solution. It is proposed that CdS particles are formed both in the interlayer region and on the external surface. Figure 12 shows

Figure 12. Scheme of CdS/ $K_4Nb_6O_{17}$ -catalyzed MV^{2+} formation using methanol as a reductant under visible light ($\lambda > 420$ nm) irradiation. From Ref. [27].

the mechanism proposed for the catalytic reaction. During the photocatalytic reduction of MV^{2+} , the amount of hydrogen produced was negligible.

Methylviologen and H^+ / $K_4Nb_6O_{17}$

Nakato et al. have intercalated $K_4Nb_6O_{17}$ with methylviologen by direct exchange of K^+ in aqueous solutions [28–31]. By carrying out reactions under two different conditions, they obtained two types of intercalates with differing amounts of MV^{2+} (Table 5). On band-gap irradiation, an intense blue color was observed, indicating the formation of $MV^{\cdot+}$ in the interlayers. The radical cations have high stability not only in vacuum but also in air and O_2 . The half-lives of the two systems are given in Table 5. It was found that the stability of $MV^{\cdot+}$ is higher in the case of $(MV)_{0.3}H_{0.7}K_{2.7}Nb_6O_{17}$. This is interpreted as being due to the spatial separation of the MV^{2+} ions by the co-existing K^+ ions, which prevents the inter-radical inter-

Table 5. Compositions and properties of MV^{2+} -intercalated $K_4Nb_6O_{17}$.

Composition	Basal spacing/nm	Half-life			Ref.

action. Figure 13 gives a schematic representation of the structures of the two intercalates.

Kameyama et al. [27] reported on UV light-assisted reduction of MV^{2+} in water and in aqueous alcohols, in the presence of partially exchanged niobate, $H_{2.4}K_{1.6}Nb_6O_{17}$. Figure 14 shows the concentration of MV^{+} produced as a function of time in water and various aqueous alcohol solutions. It is found that methanol is the best reductant for MV^{2+} reduction.

Figure 15 shows the proposed mechanism for MV^{2+} reduction in aqueous methanol solutions. It should be noted that methanol oxidation proceeds to form CO_2 , without any detectable amounts of partially oxidized products, $HCHO$ or $HCOOH$, which suggests that intercalated methanol is completely oxidized in the interlayer space. Also, no noticeable amount of H_2 was detected, indicating that H^+ ions do not compete with MV^{2+} ions for capturing photogenerated electrons from the niobate sheets. The amount of MV^{+} leveled off with continued irradiation.

Photolysis of HI by $K_{4-x}H_xNb_6O_{17}$ loaded with Pt and sensitized with $Ru(bpy)_3^{2+}$

Mallouk and co-workers [6, 26, 206] reported the photodecomposition of acidic KI to H_2 and iodine under visible light irradiation. For this purpose, $K_4Nb_6O_{17}$ was internally loaded with Pt, ion exchanged partially with acid to obtain $K_{4-x}H_xNb_6O_{17} \cdot nH_2O$ ($x \approx 2.5$) and then sensitized with RuL_3 ($L = 4,4'$ -dicarboxy-2,2'-bipyridine). It was found that KI is the best reactant among the alkali metal iodides (Figure 16).

A sensitizer concentration of 5×10^{-7} mol g^{-1} , at which a monolayer of the sensitizer molecules on the external surface of the niobate would be formed, was found to be ideal for efficient photocatalysis. At higher concentrations, the activity diminished. Also, an initial Pt loading of 0.05 wt.% and a reduction temperature [for reducing $Pt(NH_3)_4^{2+}$ to Pt] of $450^\circ C$ were found to be optimum for this system.

It was proposed that the photoreduction involves production of H_2 in the interlayer sites and formation of iodine near the sensitizer molecule, as depicted in Fig-

Figure 14. Effect of reductants, (a) methanol, (b) ethanol, (c) 2-propanol and (d) water, on the photoreduction of MV^{2+} catalyzed by $H^+/K_4Nb_6O_{17}$. From Ref. [27].

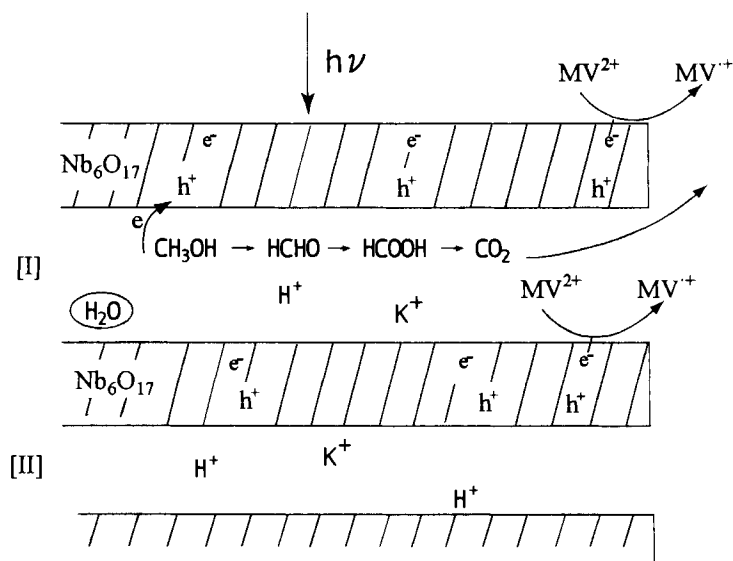

Figure 15. Schematic representation of $H^+/K_4Nb_6O_{17}$ -catalyzed MV^{2+} formation using methanol as reductant under band gap irradiation. From Ref. [27].

Figure 16. Photocatalytic H_2 evolution from $RuL_3^{2+}/K_2H_2Nb_6O_{17}/Pt$ (0.05 wt.%) in 0.7 M iodide solutions at pH 3. Reprinted with permission from Y. Kim, S.J. Atherton, E.S. Brigham and T.E. Mallouk, *J. Phys. Chem.* **1993**, 97, 11802. Copyright 1993 American Chemical Society.

ure 17. The initial quantum yield for product formation was about 0.3 %. The rate of the photolysis decreases with time, the reason given being the interception of photogenerated electrons by the reaction products (I_2^- and I_3^-), and *not* the reverse reaction. Since the reverse reaction was not operative, the concentration of the products did not change in the dark. The initial quantum yield was increased to 3 % when the reaction between the conduction band electrons and I_3^- ions was suppressed by electrostatically repelling the latter from the oxide surface through an anionic polyelectrolyte layer that was pre-adsorbed on the niobate surface [206].

Time-dependent measurements, where the transient concentration of ground-state sensitizer that was being formed by the reverse electron transfer from the layered oxide to RuL_3^{3+} was monitored as a function of time employing reflectance flash photolysis (in the absence of I^-), reveal a very slow reverse electron transfer. It is estimated that the process of reverse electron transfer is at least three orders of magnitude slower than the forward transfer.

Pillared $K_{4-x}H_xNb_6O_{17}$

Attempts have been made by Sato et al. [23–25, 32] to pillar proton-exchanged $K_4Nb_6O_{17}$ with TiO_2 , Fe_2O_3 and $Cd_{1-x}Zn_xS$. It is reported that incorporation of TiO_2 in the interlayer region enhances water cleavage on band-gap irradiation. On the basis of decreased fluorescence intensity and increased decay time constant of these pillars, it is argued that on irradiation, the photogenerated electron in the pillar is transferred to the layered host. Table 6 summarizes the results. Interestingly, the iron oxide intercalated material shows catalytic activity for irradiation with $\lambda > 400$ nm, whereas unsupported iron oxide found to be inactive.

4.2.2 KTiNbO₅-type Oxides

Titanates and titanoniobates of the general formula A_{2-x}Ti_{n-x}Nb_xO_{2n+1} (A = alkali metal) crystallize in layered structures possessing [Ti_{n-x}Nb_xO_{2n+1}]^{(2-x)-} sheets stacked with interlayer A⁻ ions [1, 2]. The sheets may be obtained from edge-connected layers of double-ReO₃ units by shearing every *n*-octahedron perpendicular to the sheets. Idealized structures of some of these oxides are shown in Figure 1. Several oxides in this family are known to exhibit interlayer chemistry

such as ion exchange and intercalation [1]. Ion-exchange reactions have been reported for Ti₂Ti₄O₉ [44], H₂Ti₄O₉ [68, 207–209], K₃Ti₅MO₁₄ (M = Nb or Ta) [45], H₃Ti₅NbO₁₄ [46], KTiMO₅ (M = Nb or Ta) [47], and HTiNbO₅ [48]. Intercalation of organic amines has been reported for H₂Ti₄O₉ [49], K₂Ti₄O₉ [210], HTi₂NbO₇ [50], HTiNbO₅ [51–54], H₃Ti₅NbO₁₄ [46], Na₂Ti₃O₇ [210], Na₂Ti₂O₅ [55] and HNb₃O₈ [211]. Kudo et al. studied luminescence properties [56, 57]. Dielectric properties have also been reported [135]. Several of these oxides have been used for photocatalysis studies. Table 7 summarizes the structural and catalysis data for these oxides. Band-gaps calculated from reflectance measurements are available for some of these oxides and are included in the table.

Shibata *et al.* [64] studied hydrogen evolution from aqueous methanol under UV irradiation catalyzed by A₂Ti_{*n*}O_{2*n*+1} (A = Na or K, *n* = 2, 3, 4 and 6) and by partially (about 80–100 %) proton-exchanged products, with and without Pt loading. Table 8 lists the H₂ evolved from these oxides. It was found that, during a 10 h observation period, the catalytic activity remained stable after a short (about 2 h) induction period. Inoue et al. [61] carried out photodecomposition of water using these oxides with Ru as a promoter. It was found that whereas considerable amounts of hydrogen were produced, no oxygen was liberated. Sato et al. carried out studies with H₂Ti₄O₉ [23–25]. In water photolysis experiments, no activity was detected even after Pt-loading. However, on pillaring with TiO₂ or Fe₂O₃, considerable activity was observed for water decomposition and/or hydrogen evolution from aq. Na₂SO₃ solution.

Sekine et al. [72] studied CsNbTiO₅, CsNbTi₂O₇ and proton-exchanged compounds for hydrogen evolution from aqueous methanol and oxygen evolution from aqueous AgNO₃ solution. Flat-band potentials for these materials were determined

by the slurry electrode method and the band-gaps were estimated from reflectance spectra. Table 7 includes the flat-band potentials and band-gaps calculated in this study. Hydrogen evolution in aqueous methanol was studied using samples both before and after Pt loading (1 wt.%). Oxygen evolution was also studied, without promoter, in aqueous AgNO₃ solutions. Table 9 lists the rates of gas evolutions under steady-state conditions. Comparing the results, we see that a striking increase in the rate of H₂ evolution was found for protonated compounds after Pt loading. This was attributed to the intercalation of methanol and the catalytic role of Pt for H₂ formation.

Nickel-loaded KTiNbO₅ was studied by Takahashi et al. [76] for the photo-decomposition of water. It was found that the activity of compounds prepared by a polymerized complex (PC) method was 10 times higher than the activity of the oxide prepared by conventional methods. The increased activity for the PC preparation was attributed partly to the larger surface area (ca. 23 vs. ca. 3 m² g⁻¹) and partly to probable improvement in surface structure.

Kim et al. [6] reported hydrogen evolution from aqueous KI/CsI solutions under visible light irradiation ($\lambda > 400 \text{ nm}$) employing several KTiNbO₅-type oxides and KNb₃O₈ (see Table 7). In these experiments, internally Pt-loaded oxides were proton exchanged and then sensitized using a monolayer of Ru-L₃²⁺ (L = 4,4'-dicarboxy-2,2'-bipyridine). All the sensitized oxides exhibited photocatalysis. There was no

Figure 18. Visible absorption spectra of MV-HTiNbO₅ (a) before and (b) after irradiation. Reproduced from T. Nakato, H. Miyata, K. Kuroda and C. Kato, *React. Solids* **1988**, 6, 231, with permission from Elsevier Science.

activity in the absence of the sensitizer. Time-dependent measurements by flash photolysis revealed that reverse electron transfer from the oxide sheets is much slower compared to the forward electron transfer from the excited RuL₃²⁺.

Nakato et al. [29–31, 78] found that photogenerated electrons from the host can be transferred to methylviologen (MV²⁺) in HTiNbO₅ intercalated with methylviologen. MV²⁺ intercalates were prepared by first exchanging about 97 % of K⁺ in KTiNbO₅ by H⁺, then treating the proton-compound with propylamine to obtain a 66 %-intercalated compound and finally treating this with aqueous methylviologen to give the final product containing 0.25 mol of MV²⁺ per mole of [TiNbO₅][−].

The MV²⁺ intercalate turns blue on UV irradiation under an N₂ atmosphere owing to the formation of MV^{•+}. Formation of the latter was confirmed by absorption measurements. Figure 18 shows the absorption spectra in the visible region (a) before and (b) after UV irradiation. It is proposed that some Ti and/or Nb are present in lower oxidation states owing to probable oxygen deficiency in the host lattice, which makes these ions electron donors. It was found that the MV^{•+} species was fairly stable in N₂, as seen from the continued appearance of blue color even after turning the UV light off. The stability indicates that the reverse reaction does not occur at a considerable rate. However, the color disappears on exposure to O₂ indicating the reaction of MV^{•+} with O₂. Similar experiments have been carried out with K₂Ti₄O₉ [29, 69] and with HNb₃O₈ [30, 31].

4.2.3 Perovskite-related Layered Oxides

Perovskite-related layered oxides showing interlamellar activity belong to two main classes, (i) the Dion–Jacobson series (DJ series) of general formula $AM_{n-1}B_nO_{3n+1}$ (e.g., $KCa_2Nb_3O_{10}$ [82]) and (ii) the Ruddlesden–Popper series (RP series) of general formula $A_2M_{n-1}B_nO_{3n+1}$ (e.g., $Na_2Gd_2Ti_3O_{10}$ [83] and $K_2La_2Ti_3O_{10}$ [84]). Their structures are characterized by n -octahedra thick perovskite-like sheets stacked with interlayer A^- ions placed in between the sheets. Figure 2 shows idealized structures of some of these oxides. An intermediate series, where the amount of interlayer ions can be varied between the above two series, is also known [85].

Structurally, three types of stacking sequences are observed in which the neighboring sheets are (i) eclipsed (e.g. $RbCa_2M_3O_{10}$), (ii) ‘staggered’ (e.g., $NaCa_2M_3O_{10}$) or (iii) partially staggered (e.g., $KCa_2M_3O_{10}$, $M = Nb$ [86] or Ta [87]).

An important aspect of these structures is the possibility of varying the thickness of sheets in multiples of octahedron thickness. Thus, in the DJ series, oxides with $n = 2$ [86, 95], $n = 3$ [13, 82, 86, 93–102], $n = 4$ [86, 96, 103, 104], $n = 5$ [96, 103, 104], $n = 6$ [96] and $n = 7$ [96] are known. In the RP series, compounds with $n = 1$ are not known. However, the $NaLaTiO_4$ -type oxides [105–109], where Na^+ -occupied interlayer planes alternate with La^{3+} -occupied interlayer planes, or the corresponding H^+ analogs [212–218], may be considered as an ordered $n = 1$ system. Higher members in this series, namely with $n = 2$ [110], $n = 3$ [83, 84, 105, 111–115] and $n = 4$ [110] are known. The possibility of varying the chemical composition by choosing appropriate elements in three positions, namely (i) cubooctahedral, (ii) octahedral and (iii) interlayer sites, is another attractive feature of these oxides. Accommodation of vacancies in cubooctahedral sites [104, 110, 115], interlayer cation sites [85, 116] and oxygen sites [117, 118] is also known. In addition, the rich interlayer chemistry, such as spontaneous hydration, ion exchangeability and intercalation of alkylamines [88, 96, 101], makes them very attractive systems for catalysis studies. Other related studies include exchange of interlayer monovalent ions with divalent ions [67, 119–121], pillaring of $HLaNb_2O_7$ with AO_2 ($A = Ti, Zr$ or Si) [219], reductive intercalation of small ions [97, 102, 122–129], luminescence measurements [105, 109, 130–134] and dielectric property measurements [135].

Several oxides in the above family have been used for photocatalytic studies, especially for hydrogen and oxygen evolution reactions. Studies on the Dion–Jacobson series are presented first, followed by studies on the Ruddlesden–Popper series and finally on the intermediate series. Table 10 lists oxides employed for photocatalysis studies.

Dion–Jacobson Series, $AM_{n-1}Nb_nO_{3n+1}$

The Dion–Jacobson series of oxides of general formula $AM_{n-1}Nb_nO_{3n+1}$, ($A = K, Rb$ and Cs , $n = 2, 3$ and 4 , and protonated analogs) was investigated by Domen et al. [13] for hydrogen evolution from aqueous alcohol (with and without Pt loading) and for oxygen evolution from aqueous $AgNO_3$, under UV irradiation. Band-gaps were estimated from diffuse reflectance spectra. The photocatalytic per-

formance of these oxides is presented in Table 11. In these samples, Pt was loaded by the photodeposition method, from H₂PtCl₆ in aqueous methanol solution. Since PtCl₆²⁻ is an anion, it is not intercalated in the host oxide. Therefore, loaded-Pt particles are deposited on the external surface of the layered perovskite powder, and were observed by TEM [137].

It can be seen in Table 11 that the activities of protonated compounds are better than those of the non-protonated counterparts. The higher activity towards hydrogen evolution has been attributed to the easy accessibility of the interlayer space for CH₃OH molecules, which is facilitated by the spontaneous hydration of these proton-exchanged oxides. Platinum loading enhances the activity for all compounds. Considerable activity has been observed towards O₂ evolution from aqueous AgNO₃, although the activity is much less than that of TiO₂. This is attributed to the intercalated Ag⁺ cations that work probably as recombination centers for electrons and holes.

Photocatalytic activity towards oxidation of higher alcohols has also been investigated [13, 136]. For this purpose, KCa₂Nb₃O₁₀ was used as a representative system. Table 12 presents the results together with those for TiO₂. For each of the alcohols, the activity increases in the order KCa₂Nb₃O₁₀ < HCa₂Nb₃O₁₀ < HCa₂Nb₃O₁₀-Pt. Also, the shorter the chain length, the higher is the activity, especially for proton-exchanged forms.

By pillaring the layered oxides, it is possible to increase the interlayer space to make such space available for guest molecules. Ebina et al. [136] investigated the catalytic activity of silica-pillared Ca₂Nb₃O₁₀. Effective pillaring was achieved by intercalation of TEOS into HCa₂Nb₃O₁₀. The BET surface area of the pillared material was 200 m² g⁻¹. Since the interlayer space is now accessible for the alcohol with longer alkyl chains as well, the activity with these alcohols improves to a

Table 12. Activity of $\text{Ca}_2\text{Nb}_3\text{O}_{10}$ system and TiO_2 for H_2 evolution from various alcohols.

Catalyst	Rate of H_2 evolution/ $\mu\text{mol h}^{-1} \text{g}^{-1}$				Ref.
	Methanol	Ethanol	1-Propanol	1-Butanol	
$\text{KCa}_2\text{Nb}_3\text{O}_{10}$	7	7	3	2	13
$\text{HCa}_2\text{Nb}_3\text{O}_{10}^{\text{a}}$	920	73	27	19	13
$\text{HCa}_2\text{Nb}_3\text{O}_{10}\text{-Pt}^{\text{a}}$	4700	380	40	30	13, 136

^aDegree of H^+ exchange >95 %.

greater extent. Table 12 includes the results with various alcohols. The effect of increased interlayer volume is clearly seen in an increase in performance with all alcohols and more so with 1-butanol.

The pillars are stable up to 400°C . At higher temperatures, the pillars collapse in height, as indicated by the shifting of the (001) line to higher angles in the powder X-ray diffraction patterns.

Visible light response was observed when the cubooctahedral Ca^{2+} ions in $[\text{Ca}_2\text{Nb}_3\text{O}_{10}]^-$ sheets were replaced by Pb^{2+} ions as in $\text{RbPb}_2\text{Nb}_3\text{O}_{10}$ [137]. In Figure 19, diffuse reflectance spectra of $\text{KCa}_2\text{Nb}_3\text{O}_{10}$ and $\text{RbPb}_2\text{Nb}_3\text{O}_{10}$ are shown. The reason for the absorption edge of $\text{RbPb}_2\text{Nb}_3\text{O}_{10}$ being at lower energies has not yet been fully revealed, but may be due to the interaction between $6s^2$ electrons of Pb^{2+} and $2p^6$ electrons of O^{2-} . Therefore, the top of the valence band shifts to higher electron energy and this results in a decrease in the band-gap. Figure 20 shows the time course of hydrogen evolution by this compound under visible

Figure 19. Diffuse reflectance spectra of (a) $\text{KCa}_2\text{Nb}_3\text{O}_{10}$ and (b) $\text{RbPb}_2\text{Nb}_3\text{O}_{10}$. From Ref. [137].

Figure 20. Time course of visible light-induced H_2 evolution from aqueous methanol solution over modified $\text{RbPb}_2\text{Nb}_3\text{O}_{10}$ catalysts: (a) $\text{RbPb}_2\text{Nb}_3\text{O}_{10}$; (b) Pt (0.1 wt.%) from $\text{H}_2\text{PtCl}_6/\text{RbPb}_2\text{Nb}_3\text{O}_{10}$; (c) $\text{HPb}_2\text{Nb}_3\text{O}_{10}$; (d) Pt (0.1 wt.%) from $\text{H}_2\text{PtCl}_6/\text{HPb}_2\text{Nb}_3\text{O}_{10}$; (e) Pt (0.1 wt.%) from $[\text{Pt}(\text{NH}_3)_4]\text{Cl}_2/\text{HPb}_2\text{Nb}_3\text{O}_{10}$. From Ref. [137].

light ($\lambda > 420$ nm) irradiation. Here also, as in the previous cases, $\text{HPb}_2\text{Nb}_3\text{O}_{10}$ shows better activity than the Rb form.

In this case, two types of Pt-loading procedures were adopted: (i) using H_2PtCl_6 as the precursor as described above, to produce Pt particles on the external surface of the catalyst, and (ii) using $\text{Pt}(\text{NH}_3)_4\text{Cl}_2$ to form Pt particles in the interlayer region. In the latter method, intercalation of $\text{Pt}(\text{NH}_3)_4^{2+}$ was achieved by treating $\text{HPb}_2\text{Nb}_3\text{O}_{10}$ with an aqueous solution of $\text{Pt}(\text{NH}_3)_4\text{Cl}_2$ for 1 week. This permits the formation of Pt particles in the interlayer region during photodecomposition of $\text{Pt}(\text{NH}_3)_4^{2+}$ by UV light. The locations of the Pt particles were confirmed by XPS and TEM. The catalytic activity was found to be higher (about fivefold) for the internally loaded samples. The difference in the catalytic activities for the two cases

Figure 21. Schematic representation of mechanisms of H₂ evolution over Pt/HPb₂Nb₃O₁₀: Pt exists in the interlayer region in (b) and only on the external surface in (a). From Ref. [137].

is explained as follows (Figure 21): when Pt particles are on the external surface (Figure 21a), some of the photogenerated electrons, especially those produced in the interior region of the sample, have to move from the bulk towards the Pt site. During this travel, some of them may recombine with holes, thus making the photocatalytic process less effective. On the other hand, when the Pt is located in the interlayer region (Figure 21b), the travel length is considerably shorter, which leads to effective photoreaction.

Oxides, such as $\text{ALa}_2\text{Ti}_2\text{NbO}_{10}$ ($\text{A} = \text{Rb}$ or Cs), which have different sheet composition compared with $\text{KCa}_2\text{Nb}_3\text{O}_{10}$, have been investigated for their catalytic activity for overall water decomposition after Ni loading [138]. The results are included in Table 13 in the following section.

Ruddlesden–Popper series, $\text{A}_2\text{M}_{n-1}\text{B}_n\text{O}_{3n+1}$

$\text{K}_2\text{La}_2\text{Ti}_3\text{O}_{10}$ is a typical oxide in the Ruddlesden–Popper series exhibiting interlayer reactivity [84]. It forms a hydrate with about 1–2 H₂O molecules per formula unit under ambient conditions [84, 114]. Figure 22 shows schematic structures of anhydrous and hydrated oxides. Variation of the number of waters of hydration with humidity and exposure time has been reported for the analogous compound

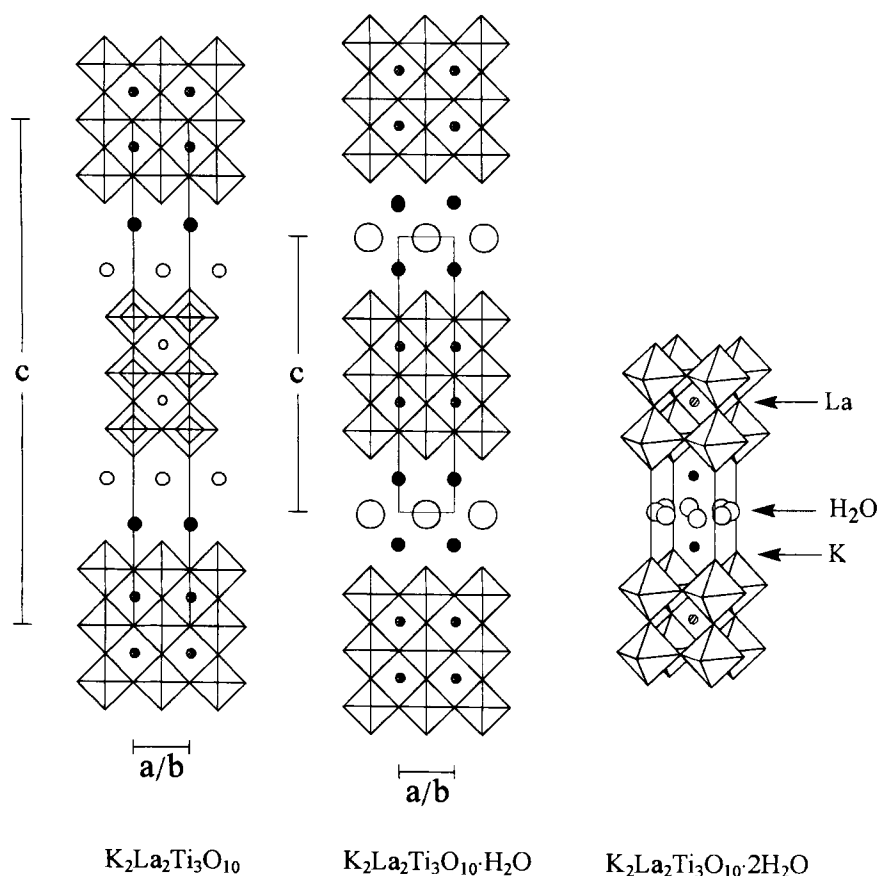

Figure 22. Schematic structures of $\text{K}_2\text{La}_2\text{Ti}_3\text{O}_{10}$, $\text{K}_2\text{La}_2\text{Ti}_3\text{O}_{10} \cdot \text{H}_2\text{O}$ and $\text{K}_2\text{La}_2\text{Ti}_3\text{O}_{10} \cdot 2\text{H}_2\text{O}$. Adapted from Refs. [84] and [114].

$\text{K}_2\text{Nd}_2\text{Ti}_3\text{O}_{10}$ [111]. A band-gap of 3.5 eV has been estimated for $\text{K}_2\text{La}_2\text{Ti}_3\text{O}_{10}$ from reflectance measurements [139].

Takata et al. [138, 139] and Ikeda et al. [140, 141] investigated $\text{K}_2\text{La}_2\text{Ti}_3\text{O}_{10}$ for photocatalysis. On loading with nickel, the oxide exhibits photocatalytic activity for overall water splitting under band-gap irradiation. The Ni-loading procedure is similar to that described earlier for $\text{K}_4\text{Nb}_6\text{O}_{17}$. The optimum amount of loaded nickel was 3 wt.%, which is considerably different from that for $\text{K}_4\text{Nb}_6\text{O}_{17}$ (0.1 wt.%). The activity depends on the KOH concentration. A 0.1 M concentration of KOH solution was the optimum for this system. Figure 23 shows a typical time course of water decomposition on Ni-loaded $\text{K}_2\text{La}_2\text{Ti}_3\text{O}_{10}$. Table 13 presents the activity data for this compound. Other promoters, such as Pt and RuO_2 , were also examined. However, only Ni was found to be effective.

Figure 23. Time course of gas evolution over $\text{K}_2\text{La}_2\text{Ti}_3\text{O}_{10}$ with optimum loading (3.0 wt.% Ni) and optimum KOH concentration (0.1 M). From Ref. [139].

A scanning electron microscopic investigation of the morphology of the Ni-loaded catalysts revealed that most of the Ni was present as small particles on the external surface of the particles. On the basis of this observation, a reaction mechanism has been proposed [138], as depicted in Figure 24. According to this mechanism, electrons and holes are generated in the $\text{La}_2\text{Ti}_3\text{O}_{10}^{2-}$ sheets on band-gap irradiation. The electrons, having higher mobility than holes, migrate on to the external surface reaching the Ni particles where H_2O is reduced to H_2 . The holes travel a much shorter distance and react with water molecules in the interlayer region to generate oxygen.

Analogous compounds, $\text{Rb}_2\text{La}_2\text{Ti}_3\text{O}_{10}$ and $\text{Cs}_2\text{La}_2\text{Ti}_3\text{O}_{10}$, have also been studied for overall water splitting [138]. The optimum Ni loading for these was slightly higher, namely 4 wt.%. The catalytic activity was about twice that of $\text{K}_2\text{La}_2\text{Ti}_3\text{O}_{10}$, as shown in Table 13.

Series with intermediate cation density

Intermediate in interlayer ion density between $\text{KCa}_2\text{Nb}_3\text{O}_{10}$ and $\text{K}_2\text{La}_2\text{Ti}_3\text{O}_{10}$ are compounds of general formula $\text{A}_{2-x}\text{La}_2\text{Ti}_{3-x}\text{Nb}_x\text{O}_{10}$, where the cation density can be varied between the end members [85]. Photocatalysis of $x = 0.5$ members has been studied by Takata et al. [138]. Band-gaps of 3.4–3.5 eV were estimated from reflectance measurements. The photocatalytic activities for H_2O decomposition under UV irradiation are also listed in Table 13.

From the observation that such layered oxides, which undergo easy hydration under normal humidity, are associated with better catalytic activity, it appears that hydration behavior is one of the factors affecting the catalytic activity.

Figure 24. Proposed reaction mechanism for photocatalytic water decomposition on Ni-loaded $\text{K}_2\text{La}_2\text{Ti}_3\text{O}_{10}$. From Ref. [138].

Table 13. Photocatalytic activities of $\text{A}_2\text{La}_2\text{Ti}_3\text{O}_{10}$, $\text{ALa}_2\text{Ti}_2\text{NbO}_{10}$ and $\text{A}_{1.5}\text{La}_2\text{Ti}_{2.5}\text{Nb}_{0.5}\text{O}_{10}$ oxides [138].

4.3 Clays

Clays are a class of silicates having layered structure, most of which occur in nature. They exhibit interlamellar reactivity, which makes them useful in catalysis. The sheets in clays consist of either two tetrahedral silicate units sandwiching an octahedral unit as in 2:1 clays or one tetrahedral unit joined to one octahedral unit as in 1:1 clays. Of these, 2:1 clays are more common in use.

Figure 25. Schematic representation of 2:1 (trioctahedral and dioctahedral) cationic clays.

In 2:1 clays, the octahedral unit may either have all the octahedral sites occupied by metal ions (as in trioctahedral clays) or have only two-thirds of the octahedral sites occupied (as in dioctahedral clays). Talc $[\text{Si}_8\text{Mg}_6\text{O}_{20}(\text{OH})_4]$ and pyrophyllite $[\text{Si}_8\text{Al}_4\text{O}_{20}(\text{OH})_4]$ have representative structures of trioctahedral and dioctahedral clays, respectively. These two clays possess no net charge in their sheets, so they do not have charged species in the interlayer region, hence the name ‘neutral clays’. When the Si^{4+} in the tetrahedral unit and/or metal ions in the octahedral unit (Al^{3+} or Mg^{2+}) are partially substituted by ions of lower charges, the sheets attain a net negative charge. Charge neutrality can be maintained if the structure accommodates an appropriate number of additional cations in the interlayer region. Such clays are called cationic clays. Figure 25 shows a schematic representation of 2:1 (trioctahedral and dioctahedral) cationic clays. The interlayer cations are usually exchangeable with other cations by simple chemical methods. Cationic clays are classified according to the amount of cations present in the interlayer region.

Montmorillonite clay has been used as a host for accommodating photo-responsive species for photocatalytic and photochemical studies. Montmorillonite is a 2:1 dioctahedral cationic clay, which derives its charge in sheets due to partial substitution of Al^{3+} in $\text{Si}_8\text{Al}_4\text{O}_{20}(\text{OH})_4$ by Mg^{2+} . When sodium is present as a charge-compensating cation in the interlayer region, it is known as sodium montmorillonite. The charge may vary between 0.5 to 1.2 per unit cell. Guest species that have been studied include pillars of TiO_2 , Fe_2O_3 , $\text{CdS} + \text{ZnS}$ and several molecular species. Here, the host acts as an inert host in that it does not directly absorb photons in photoreactions.

4.3.1 TiO_2 in Montmorillonite

Yoneyama et al. [142, 143] formed TiO_2 pillars with thickness of about 1.5 nm in the galleries of montmorillonite by intercalation of titania sol followed by decom-

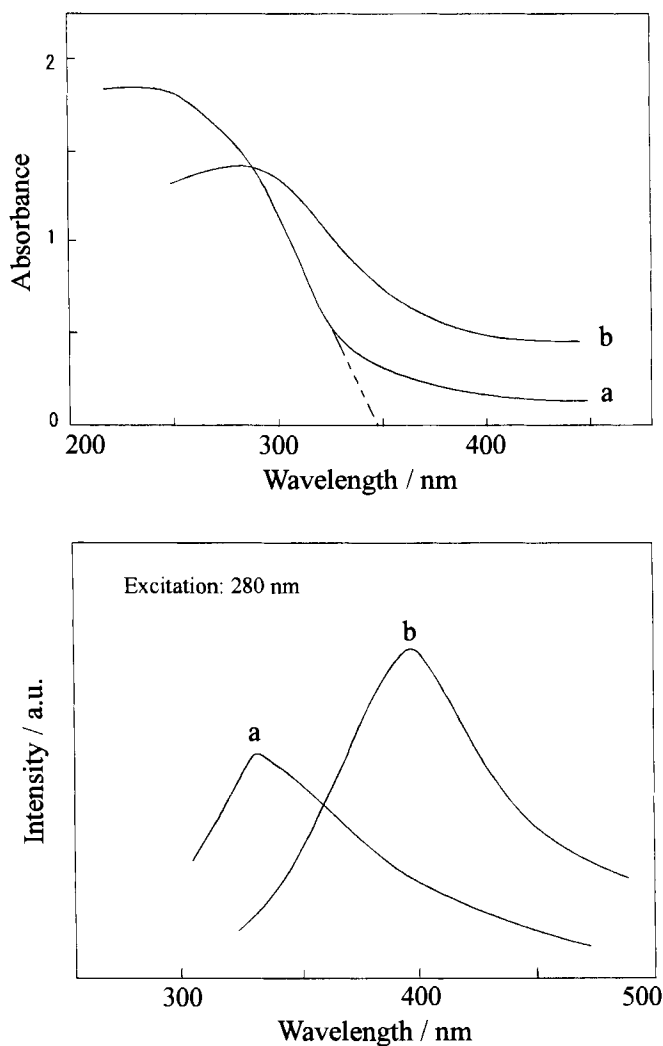

Figure 26. Absorption and fluorescence spectra of aqueous suspensions of (a) TiO₂-clay and (b) TiO₂ powder. Reprinted with permission from H. Yoneyama, S. Haga and S. Yamanaka, *J. Phys. Chem.* **1989**, 93, 4833. Copyright 1989 American Chemical Society.

position according to Yamanaka et al. [144, 145], which increased the surface area from 72 to 347 m² g⁻¹. The weight ratio of TiO₂ to clay was 1:1. The absorption and emission spectra of the TiO₂-clay system were blue shifted with respect to those of TiO₂ powders, indicating a wider band-gap in the TiO₂ pillars. Figure 26 shows the absorption and emission spectra of TiO₂-clay and TiO₂ powders. From the fluorescence blue shift, a band-gap of 3.58 eV was estimated, which is 0.58 eV greater than that of TiO₂ bulk material. This value agreed with their estimation from the absorption threshold (348 nm). From transient photocurrent measurements as a function of pH, the Fermi level of TiO₂-clay and TiO₂ powder were estimated to be -0.64 and -0.28 V vs. SCE, respectively, at pH 0.

Table 14. Photocatalytic decomposition of 2-propanol (reprinted with permission from H. Yoneyama, S. Haga and S. Yamanaka, *J. Phys. Chem.* **1989**, 93, 4833. Copyright 1989 American Chemical Society).

TiO ₂ /clay	1.34	0.35	0.12	0.15	1.4
Pt/TiO ₂ ^b	183	Trace	Trace	Trace	172
Pt/TiO ₂ /clay	697	4.0	Trace	Trace	661

^a Illumination with a 500 W high-pressure mercury arc lamp for 24 h of 3 mg of TiO₂ suspended in 8 ml of 2-propanol containing 0.2 ml of water. The data are given as time-averaged values for 24 h.

^b The amount of loaded Pt was 2 wt.-%.

The photocatalytic activity for decomposition of propanaol and various carboxylic acids has been studied, both with and without Pt loading. The activity of TiO₂-clay was found to be much higher than that of TiO₂ powder. This was attributed to the excited electronic state in pillars being higher by 0.36 eV, which is favorable for hydrogen evolution. Photodecomposition data for 2-propanol and for various acids are listed in Tables 14 and 15. As can be seen, the activity of TiO₂-clay is higher for all the acids except 1-decanoic acid. The lower activity for the latter has been attributed to the interlayer space being too narrow to accommodate large molecules.

4.3.2 Fe₂O₃ in Montmorillonite

Miyoshi and Yoneyama [146] incorporated microcrystals of Fe₂O₃ through insertion of a trinuclear complex of Fe(III) according to Yamanaka et al. [147] and studied the photodecomposition of acetic acid and propionic acid. The pillar height was about 0.66 nm as estimated from XRD. The blue shift in the absorption spectra was about 0.28 eV (Figure 27). Band-gaps of 2.48 and 2.2 eV were estimated for Fe₂O₃-clay and α-Fe₂O₃, respectively, from absorption spectra. Fermi levels at pH 0 were determined to be -0.01 and +0.22 V vs. SCE, respectively, by transient photocurrent measurements. Figure 28 shows the energy diagram. Table 16 and Figure 29 summarize the catalytic performance. Higher activity was observed for n-butyric acid also. As in the case of TiO₂-pillared clay, the higher activity was attributed to an upward shift of the Fermi level of Fe₂O₃ (Figure 28), resulting in increased reducing power.

4.3.3 CdS and ZnS Mixtures in Colloidal Montmorillonite

The mixed semiconductor system ZnS + CdS supported on Nafion films or on SiO₂ is known to liberate hydrogen from Na₂S solutions under visible light irradiation

^b With one C atom less than that in the acid.

without Pt, even though, individually, neither ZnS nor CdS is active [148]. Similar results have been reported for this system supported on colloidal montmorillonite clay [149]. Fermi levels were not determined, probably owing to the complex nature of the transient current vs. pH relationship. Comparing this system with the same system supported on SiO₂, it was reported that the activity in clay was about four times smaller.

4.3.4 Photoactive Species Intercalated into Lamellar Oxides

Layered materials serve as good hosts for accommodating photoresponsive molecular species. Ogawa and Kuroda [150] reviewed the photoprocesses in layered hosts.

Photoresponsive electron donor species such as Ru(bpy)₃²⁺ [151–159] and acceptor species such as MV²⁺ (MV = methylviologen) [153, 160] have been intercalated into montmorillonite/kaolin clays. Luminescence of Ru(bpy)₃²⁺ was found to be strongly quenched by lattice Fe³⁺ [152, 154]. A random distribution of quenching sites in the lattice has been proposed [155]. Self-quenching due to segregation has also been reported [153]. The segregation of Ru(bpy)₃²⁺ from co-intercalated

MV²⁺ results in poor quenching by the latter compared with the quenching efficiency in homogeneous solutions. Co-intercalation of photoinactive Zn(bpy)₃²⁺ results in decreased self-quenching due to the random distribution of the luminescent molecules and the inactive molecules [153]. Also, whereas neutral propylviologen sulfonate (PVS) was found to be an effective quencher, MV²⁺ was not [153]. Studies with the aim of understanding racemic interactions between the optically active isomers of Ru(bpy)₃²⁺ have also been reported [156–158]. It may be noted that only 50 % intercalation of Ru(bpy)₃²⁺ occurs when the reactant contains only one isomer, whereas 100 % intercalation proceeds for racemic mixtures. Intercalation with a sequential arrangement of Δ - and Λ -isomers has been proposed for this observation [161, 162].

Hydrogen evolution under visible light irradiation, using triethanolamine as sacrificial electron donor, has been reported for the MV²⁺-clay (montmorillonite and

2.5	1.5	3.9
5.0	3.0	5.4
7.5	4.5	4.3
10.0	6.0	6.3

^aOther conditions: $Ru(bpy)_3^{2+}$ (5×10^{-4} M), triethanolamine (0.1 M), pH 7.0, argon atmosphere, 300 W tungsten halogen lamp, $\lambda > 395$ nm.

hectorite) system catalyzed by $Ru(bpy)_3^{2+}$ [163, 164]. The MV^{2+} to clay ratio was three times the cation exchange capacity of the clay. The internal surface was covered exclusively by MV^{2+} whereas the external surface was covered by MV^{2+} and $Ru(bpy)_3^{2+}$ in a 3:1 ratio. The excess MV^{2+} remained in solution. Nine different systems, differing in initial interlayer cations, were studied and the properties were found to be the same for all of these clays. Table 17 gives the results of a typical experiment.

Visible light-induced cleavage of water has been reported for a mixed colloidal clay system consisting of a mixture of sepiolite clay- RuO_2 - $Ru(bpy)_3^{2+}$ colloid (for O₂ production) and $Al_xEu_{1-x}(OH)_3$ -Pt colloid (for H₂ production) [165]. A turn-over number of 20 with respect to the sensitizer, $Ru(bpy)_3^{2+}$, was observed. It was reported that the gas (H₂ + O₂) evolution displayed a damped oscillatory behavior. Photo-oxidation of water by *trans*-diaqabis-(2,2'-bipyridine)ruthenium(2+) adsorbed on the surface of hectorite clay has also been reported [166].

A brief mention about gas evolution at clay modified electrodes, which is desirable in electrocatalysis, was made by Bard and co-workers [167, 168]. It should be noted that metal-bpy complexes and MV^{2+} bound on the internal and external surfaces of montmorillonite clay are *electroinactive*, and only about 15–30 % of the external electroactive species, which probably are present as ion pairs [170], reach the electrode [169].

4.4 Layered Double Hydroxides (LDHs) [171–174]

Layered double hydroxides, also known as anionic clays, belong to a class of lamellar hydroxides with a structure related to that of brucite. A large number of these hydroxides are naturally available and many more have been synthesized in laboratories. The structure of brucite, $Mg(OH)_2$, consists of sheets of edge-connected $Mg(OH)_6$ octahedra, which are held together by means of Van der Waals forces. The sheets have the composition $Mg(OH)_2$, and are electrically neutral.

Figure 30. Schematic structure of anionic clays. A represents an anion.

When part of Mg^{2+} is replaced by an ion with higher charge, such as Al^{3+} , the sheets attain a positive charge. Overall charge neutrality is maintained through accommodation of anions in the interlayer region. Thus, substitution of 25 % of Mg^{2+} sites by Al^{3+} and placing CO_3^{2-} cations in the interlayer region, together with water molecules, give the formula $\text{Mg}_{0.75}\text{Al}_{0.25}(\text{OH})_2(\text{CO}_3)_{0.125} \cdot \frac{1}{2}\text{H}_2\text{O}$, which is the ideal composition of the mineral, hydrotalcite. Figure 30 gives a schematic view of the hydrotalcite structure.

The general formula of hydrotalcite-like compounds can be given as $\text{M}^{2+}_{1-x}\text{M}^{3+}_x(\text{OH})_2 \text{A}^{n-}_{x/n} \cdot m\text{H}_2\text{O}$, where $\text{M}^{2+} = \text{Mg}^{2+}, \text{Fe}^{2+}, \text{Co}^{2+}, \text{Ni}^{2+}, \text{Cd}^{2+}, \text{Cu}^{2+}$ or Zn^{2+} , $\text{M}^{3+} = \text{Al}^{3+}, \text{Ga}^{3+}, \text{Cr}^{3+}$ or Fe^{3+} and $\text{A}^{n-} = \text{CO}_3^{2-}, \text{SO}_4^{2-}, \text{OH}^-, \text{F}^-, \text{Cl}^-, \text{Br}^-$ or NO_3^- . The charge density of the hydroxide sheets depends on the $\text{M}^{2+}/\text{M}^{3+}$ ratio. Pure LDHs can be synthesized usually for $0.2 \leq x \leq 0.33$. Two types of stacking sequences of sheets are found, giving 2H and 3R structures. The interlayer anions (except CO_3^{2-}) can easily be exchanged by organic anions (such as carboxylates and sulfonates) and polyoxometallate anions.

4.4.1 Photocatalysis in LDHs Intercalated with CdS and CdS/ZnS

Sato et al. [175] reported on photocatalytic hydrogen evolution by CdS and CdS/ZnS (species obtained by sequential formation of CdS and then ZnS) incorporated into MgAl-LDH. The size of the sulfide particles was estimated to be about 0.3 nm. The optical absorption shows a slight blue shift, e.g. from 2.46 eV for bulk CdS to 2.64 eV for LDH-CdS. Photocatalytic hydrogen evolution was studied by using Na_2S and Na_2SO_3 as sacrificial electron donors. It was found that efficient H_2 evolution takes place in the intercalated system, although at a lower rate than that of the unsupported system, CdS/ZnS. The lower activity has been attributed to the restricted mass transfer in the interlayer region.

4.4.2 Photocatalysis in LDHs Pillared with Polyoxometallates

Polyoxometallates of Mo and W in homogeneous solutions are known to photocatalyze oxidation of alcohols [176, 177]. Such species can be intercalated into

the interlayer galleries of LDHs by ion-exchange reactions giving pillared structures with fairly high surface area. Kwon et al. [178, 179] synthesized several polyoxometallate-pillared LDHs and demonstrated photocatalytic properties for representative cases. Thus $\text{Zn}_2\text{Al}(\text{OH})_6\text{Cl} \cdot 2\text{H}_2\text{O}$ after pillaring with $\text{V}_{10}\text{O}_{29}^{6-}$ and $\text{Zn}_2\text{Al}(\text{OH})_6(\text{NO})_3 \cdot m\text{H}_2\text{O}$ after pillaring with polytungstates ($\text{BV}^{4+}\text{W}_{11}\text{O}_{40}^{11-}$, $\text{SiV}_3\text{W}_9\text{O}_{40}^{7-}$ or $\text{H}_2\text{W}_{12}\text{O}_{40}^{6-}$) oxidize catalytically 2-propanol to acetone under irradiation with light with $\lambda > 390$ nm in an oxygen atmosphere. Turnover numbers of 4–10 have been reported.

4.4.3 LDHs Intercalated with Photoresponsive Species

Robins and Dutta studied MV^{2+} reduction, in the presence of EDTA as sacrificial electron donor, by a *visible* light-excited Zn–porphyrin complex that was intercalated into LDH–tetradecanoate [180]. The rate of formation of viologen radical was higher when propylviologen sulfonate (PVS) was used. When TiO_x on the external surface (formed by hydrolysis of titanium butoxide) was present instead of intercalated Zn–porphyrin complex, UV light ($\lambda = 350$ – 450 nm)-assisted formation of viologen radicals was observed. The system, in which both the Zn complex and TiO_x were present, was also effective in the visible region ($\lambda = 420$ – 650 nm). It is argued on the basis of experimental results that, in this last system, sensitization of TiO_x particles by Zn–porphyrin complex *does* take place.

The luminescent anion $\text{Ru}(\text{BPS})_3^{4-}$ (PBS = 4,7-diphenyl-1,10-phenanthroline disulfonate) was intercalated into MgAl–LDH by Giannelis et al. [181]. Luminescence decay measurements indicated efficient self-quenching of the $\text{Ru}(\text{BPS})_3^{4-}$ emission. On co-intercalation of nonemissive $\text{Zn}(\text{BPS})_3^{4-}$, the self-quenching still persists and is attributed to the segregation of emitting ions. However, at higher concentrations of the Zn complex ($\text{Ru}:\text{Zn} = 1:9$), the emission kinetics of $\text{Ru}(\text{BPS})_3^{4-}$ were similar to the kinetics in solutions, indicating sufficient separation of emitting molecules in the galleries.

4.5 Artificially Built Multilayer Systems

Artificially built layered structures consisting of several components are attractive systems of interest in solid-state microelectronics, electrochemistry and catalysis [182, 183]. At present, artificial building has reached the level of incorporating desired species in a desired layer to obtain predictable properties [184, 185].

The deposition of molecular films on solid substrates was initially of the Langmuir–Blodgett type [186, 187], where layers preformed on a liquid–air interface are carefully transferred on to a solid surface. The difficulties associated with deposition of LB films are overcome in systems where molecules from a solution phase assemble themselves on a solid surface in the form of a one molecule thick film. If the interaction between the head groups of the molecules with the substrate surface is of the covalent type, as in the case of surface silanization [188, 189], then we can expect the film to be mechanically robust.

Figure 31. Chemisorption of *n*-octadecyltrichlorosilane on a glass slide. Reprinted with permission from J. Sagiv, *J. Am. Chem. Soc.* **1980**, 102, 92. Copyright 1980 American Chemical Society.

Various types of substrates have been used for layer deposition. Materials used as substrates include glass [188], SnO_2 [190], Al [188], Pt [191] and Au [192, 193]. In the case of glass or SiO_2 , the substrate surface is treated with alkylsilanes to form a 'primer' coating (anchor layer) on the surface. When gold is used as the substrate, thiols are found to be suitable for the anchor layer. Figure 31 shows the proposed bonding scheme for chemisorption of *n*-alkyltrichlorosilane on a silica glass surface.

Films grown in this manner are usually characterized by techniques such as ellipsometry, atomic force microscopy (AFM) and cyclic voltammetry. Ellipsometry gives the thickness of the layers and AFM the surface uniformity. Cyclic voltammetric measurements can give information about electron transfer across the film.

Once the anchoring layer has been deposited, a second layer can be grown on top of this layer when the tails of the molecules in the first layer are functionalized to link covalently to the head groups of the molecules in the second layer [189]. Figure 32 shows the scheme of formation of zirconyl phosphate layers. By repeating the deposition steps, such as steps 2 and 3 in Figure 32, a number of times, it is possible to deposit multilayer films [182, 183, 194].

Instead of covalent binding, an ionic bonding scheme can also be used. Thus, thin films of polymeric species are deposited by this method [195] (Figure 33).

Two-component systems, where one of the components is a polymeric film and the other is a clay sheet [196, 197], $\alpha\text{-ZrP}$, $[\text{Ti}_2\text{NbO}_7]^-$, $[\text{K}_2\text{Nb}_6\text{O}_{17}]^{2-}$ sheet [198], $[\text{Ca}_2\text{Nb}_3\text{O}_{10}]^-$ sheet [199] or graphite sheet [200], have been built. A combined ionic and covalent scheme can also be used as demonstrated [201] (Figure 34).

4.5.1 Towards Photoinduced Charge Separation

When viologens (MV^{2+}) are incorporated as part of the zirconium phosphate layers, and the resulting films are irradiated with solar radiation, stable viologen radicals

are produced, possibly by electron transfer from halide (Cl^- or Br^-) to MV^{2+} [202]. When porphyrins and viologens were incorporated as above in separate layers and irradiated with the excitation of porphyrin, the fluorescence of photoexcited porphyrin was quenched, indicating charge transfer from porphyrin donor to MV^{2+} acceptor [203]. In other methods, donor and acceptor species have been embedded in the multilayer films using the ability of polymeric ions to form monolayer films. For example, polymeric allylamine hydrochloride (PAH) was tagged with donor fluorescein (FI) and acceptor Rhodamine B (RHB) and the two species were confined to separate layers by sequential adsorption, with or without intermediate α -zirconium phosphate spacer layers [204]. Table 18 lists some such assemblies.

In steady-state fluorescence emission studies of these systems, good agreement between the experimental and theoretically calculated energy transfer efficiencies has been observed (Table 18), which indicates that the efficiencies in these systems are predictable. This is highly desirable in designing systems with high efficiencies.

Such multilayer systems can also be assembled on nonflat surfaces [185, 205]. Figure 35 shows the building scheme of a heterostructure on silica particles. In this case, MDESA-mediated electron transfer from Ru^{2+} to MV^{2+} proceeds through the following steps:

A multilayer system for photon harvesting from a wider region of visible light and to form a long-lived charge-separated state was built by Mallouk and co-workers [184, 185]. Two typical layer sequences are shown in Figures 37 and 38. In this system, coumarin, fluorescein, Pd-porphyrin and MV²⁺ (Figure 36) form an energy-harvesting chromophore group making a donor-acceptor sequence.

Molecules of chromophores were attached to appropriate ionic polymers to allow their confinement in desired layers. Good spectral overlap between donor emission and acceptor absorption spectra permits efficient energy transfer in the supramolecular assembly. Figure 36 summarizes the spectral characteristics of the four photoactive species [184]. The coumarin polymer (Coum-PAH) absorbs in the blue region of the visible spectrum ($\lambda_{\text{max}} = 412 \text{ nm}$), and its emission maximum, 485 nm,

Figure 37. Steady-state emission spectra ($\lambda_{\text{ex}} = 450$ nm) of adsorbed monolayers of Coum-PAH and FI-PAH polycations, PdTAPP⁴⁺ and the co-adsorbed coumarin–fluorescein–porphyrin triad. Reproduced from D.M. Kaschak, S.A. Johnson, C.C. Waraksa, J. Pogue and T.E. Mallouk, *Coord. Chem. Rev.* **1999**, 185–186, 403, with permission from Elsevier Science.

coincides with the intense absorption band of the fluorescein polymer, FI-PAH ($\lambda_{\text{max}} = 500$ nm). The Coum-PAH emission also overlaps with the Q-band absorptions of porphyrin molecules. The emission maximum of FI-PAH (530 nm) completely overlaps the porphyrin Q-band absorbance maximum. In addition, porphyrins have a strong Soret absorbance band in the blue region. Together, these three chromophores are strong absorbers in the 380–530 nm region. The PVT–MV²⁺ polymer does not absorb in the visible region and so does not participate in the energy-transfer sequence. However, MV²⁺ is a good electron acceptor and is capable of accepting an electron from excited porphyrins.

In Figure 37, the photon-absorbing species are co-adsorbed in a single layer and the electron acceptor species is not present. Figure 37 also shows the emission spectra of the multilayer system, for exciting in the coumarin absorption band ($\lambda = 450$ nm). Luminescence spectra of single-component systems are also included. It is seen that efficient energy transfer takes place in this assembly: there is nearly complete quenching of the coumarin emission at 485 nm, substantial quenching of fluorescein emission at 530 nm and greatly enhanced porphyrin emission at 720 nm, with reference to individual emissions. The energy transfer quantum efficiency (χ) is 0.81 for this system. When the antenna molecules were placed in separate layers, χ was equal to 0.65.

Addition of an inorganic sheet and a PVT–MV²⁺ layer results in efficient quenching of the porphyrin phosphorescence at 720 nm, due to electron transfer from excited porphyrin to MV²⁺. Electron-transfer quantum yields were calculated as 0.58 and 0.76 for α -ZrP and HTiNbO₅ spacers, respectively. Figure 38 shows the steady-state emission spectrum of such a multilayer system.

Spectroscopic transient-state measurements indicate fast, biexponential electron transfer from porphyrin to MV²⁺, with either α -ZrP or HTiNbO₅ spacer sheets

Figure 38. Emission spectra ($\lambda_{\text{ex}} = 450$ nm) of the photon-harvesting assembly having an electron-receiving PVT-MV²⁺ layer. Reprinted with permission from D.M. Kaschak, J.T. Lean, C.C. Waraksa, G.B. Saupe, H. Usami and T.E. Mallouk, *J. Am. Chem. Soc.* **1999**, 121, 3435. Copyright 1999 American Chemical Society.

(Figure 38). Of these, the HTiNbO₅ spacer efficiently blocks the reverse electron transfer.

4.6 Conclusion

Layered oxide systems belonging to different structural families, such as KTiNbO₅-type oxides, perovskite-related oxides, cationic clays and layered double hydroxides, provide a large number of materials with interlayer reactivity which can be employed in electron-transfer applications. In each of these families, the chemical composition of the systems can be varied without altering the main structural features, which provides a route for varying the composition-dependent properties such as acidity and hydration. Perovskite-related layered oxides are especially useful in this regard since an appropriate choice of cations can be made in octahedral and cubo-octahedral sites, in addition to interlayer sites. Also, vacancies can be accommodated in cubo-octahedral sites, interlayer sites and oxygen sites. This gives additional parameters, which can be varied in order to obtain desired material properties. Some of these oxides, and also other layered oxides, have already been used as electron-transfer systems as described in this chapter. The photogenerated electrons and holes have successfully been used for decomposing water into hydrogen and oxygen.

The photon absorption efficiency of the oxides can be greatly enhanced by the adsorption of organic dye molecules on the surface of the oxides. Such sensitized systems are promising in giving efficient electron-transfer systems.

Exploiting the weak interlayer chemical bonding in these oxides, the structures can be broken to form single sheets, as in exfoliation, where the two-dimensional structural integrity of the sheets is still retained. Such exfoliated sheets can be re-assembled by employing a layer-by-layer deposition technique together with other inorganic or organic layers in a desired sequence. Such techniques may be employed in designing and testing new application-oriented systems.

5 Fundamental Aspects of Electron Transfer in Substrate-supported Organized Molecular Assemblies

Robert S. Clegg and James E. Hutchison

5.1 Introduction

Monolayer and multilayer thin films are technologically important materials that potentially provide well-defined molecular architectures for the detailed study of interfacial electron transfer. Perhaps the most important attribute of these heterogeneous systems is the ease with which their molecular architecture can be synthetically varied to tailor the properties of the ensemble. Assemblies incorporating specifically designed structures can, in principle, meet the needs of a variety of technological applications and be used as models for understanding fundamental interfacial reaction mechanisms. In fact, molecular assemblies are nearly ideal ‘laboratories’ for the fundamental study of electron-transfer reactions at interfaces. In this chapter, the use of monolayer and multilayer assemblies to probe fundamental questions regarding electron transfer in surface-confined molecular assemblies will be addressed.

Electron-transfer reactions in heterogeneous media are among the most important fundamental reactions in chemistry and biology, yet they remain to be completely understood. Heterogeneous electron-transfer processes are at the heart of technologically important systems, including processes at electrodes (e.g., electrocatalysis, chemical sensing and corrosion prevention), solar energy conversion, imaging (e.g., xerography and photography) and micro- and molecular electronics [1–3]. Complex heterogeneous biological systems permit exquisite control over the rates and directionality of electron transfer (e.g., the organized assemblies within membranes that are responsible for important processes such as oxidative phosphorylation and photosynthesis) [4]. Despite extensive study, the roles of electron-transfer reactions in artificial and biological systems continue to broaden. *The overarching goal of the investigations described within this chapter is understanding electron transfer in designed heterogeneous systems and, to a lesser extent, utilizing these systems for applications.*

Homogeneous systems have been extensively studied and most of the important parameters that affect electron transfer are established [5]. On the other hand,

electron-transfer processes in the more complex *heterogeneous* architectures are less well understood. Nevertheless, studies on homogeneous systems provide useful lessons (and a starting point) for understanding the more complex heterogeneous systems. Comprehensive theoretical treatments [6, 7] and numerous experimental investigations have been carried out on homogeneous systems. From this work, the dependence upon electron-transfer distance, molecular orientation, thermodynamic driving force, nature of the chemical environment (including solvent polarity and interactions), molecular spacer composition and temperature have been largely determined and are summarized concisely in a review by Bolton et al. [5]. The ability to obtain quantitative data on homogeneous populations of discrete, defined molecular systems using well-developed analytical tools (single-crystal X-ray diffraction, solution spectroscopic tools, etc.) has made these advances possible.

Why is it harder to determine how electron transfer depends upon structural and chemical parameters for heterogeneous systems? First, the nature of a heterogeneous system increases the probability that an inhomogeneous population of redox partners exists. The ideal system would be a defect-free sample where all electron-transfer partners were identically situated and would therefore exhibit the same kinetics. Such samples are difficult to prepare. Second, defects within a sample are often difficult to detect given the available structural tools that typically probe the bulk structure of an assembly. One often must rely upon indirect evidence (e.g., a single rate constant for electron transfer) of the structural homogeneity of electron-transfer assembly. To summarize, the difficulty in studying these heterogeneous systems is that *structural and compositional parameters that are hard to control (or determine) in molecular assemblies will affect electron-transfer rates*. Thus, the key challenge in performing detailed investigations of electron-transfer reactions in synthetic heterogeneous molecular assemblies is to strive continually to obtain better control over structure and make use of the best analytical methods that can detect inhomogeneous electron-transfer paths and/or defects within the sample.

Organized assemblies such as monolayer and multilayer thin-film samples offer a number of advantages as models with which to understand the fundamental aspects of electron transfer in heterogeneous systems:

- 1) Close-packed thin films enforce a conformational rigidity and thus impose a well-defined distance between redox partners, even if the bridge alone is not rigid.
- 2) The thin-film environment eliminates diffusion or reduces it to a low level.
- 3) Noncovalent organization of well-defined building blocks provides access to a large number of structural combinations without additional synthesis.
- 4) Assemblies on solid substrates can frequently be more easily analyzed with direct structural probes than heterogeneous aggregates in solution.
- 5) Organized assemblies provide a closer approximation to natural or synthetic organized assemblies than solution species.
- 6) In the case of conducting substrates, the electrode provides an infinitely tunable electrochemical driving force for electron transfer.

In the sections that follow, we will first outline the approaches that have been taken to use molecular assemblies to understand interfacial electron transfer and the

challenges faced in developing these systems. Next, the progress toward understanding electron transfer in well-defined assemblies will be discussed with emphasis on the interplay between structural parameters and electron-transfer kinetics in these assemblies. Finally, some of the continuing challenges and future directions of electron-transfer studies in molecular assemblies will be discussed.

5.2 Background

5.2.1 Monolayer and Multilayer Systems

Monolayer and multilayer assemblies supported on solid substrates *ideally* provide thin films of precise thickness and well-defined composition for the detailed study of the fundamental aspects of electron-transfer events in heterogeneous environments. These assemblies offer exquisite control over essentially all desirable experimental variables, including electron-transfer distance, molecular bridge chemical composition, redox probe or chromophore orientation, driving force for electron transfer, surrounding chemical environment, etc. In addition, the building blocks that make up these assemblies can be arranged on a variety of insulating and conducting substrates.

The challenge in employing these assemblies to obtain quantitative electron-transfer data is making sure that measurements made actually reflect the properties of the *intended* molecular architecture. In fact, electron-transfer measurements on such systems are often dominated by defects within the assembly or are made complex by multiple types of electron-transfer pathways within the film. Further complicating the situation is the fact that most available analytical tools provide data that are dominated by the bulk properties of the assembly rather than the local structure of the electron-transfer paths. Hence great care must be exercised in designing, assembling, characterizing and studying these assemblies so that data reflect the desired experimental system and are not the result of film defects, disorder or lateral heterogeneity.

Electron-transfer investigations have been made using both monolayer and multilayer assemblies prepared either by Langmuir–Blodgett techniques or through chemical self-assembly. Examples illustrating common structural motifs are shown in Figure 1. In the remainder of this section, the methods for preparing these assemblies will be briefly reviewed. Next, the relative strengths and limitations of each type of architecture and assembly method with respect to ease of preparation, experimental flexibility and structural integrity will be discussed. Finally, the methods used and challenges faced in characterizing these assemblies will be addressed.

Langmuir–Blodgett (LB) films

LB mono- and multilayers have been extensively studied as thin films with well-defined internal molecular architecture. This well-known method [8–13] involves a

Figure 1. The use of monolayer and multilayer assemblies for electron-transfer study. Numerous other possible arrangements are not shown. (A) Mono- or multilayer on a conducting substrate (electrode) with pendant or soluble (not shown) redox probe. (B) Monolayer assembly on an insulating substrate with electron donors and acceptors in the same molecular chain. (C) Multilayer assembly with electron donors and acceptors in different layers of the assembly.

two-step process. In the first step, an organized monomolecular layer (Langmuir layer) of one of the components of the film is formed on an aqueous subphase. During the second step, the compressed Langmuir layer is transferred (by passing a clean substrate through the air–water interface) onto an appropriate support to form the LB film. The mechanism of transfer is not completely understood despite extensive study—obtaining complete transfer of the film and a *well-organized* assembly on the substrate can be difficult. In fact, the deposition conditions (including surface pressure during deposition, transfer speed, subphase composition and temperature) must be optimized for each new film building block [14].

The LB method is especially useful for preparing multilayered molecular assemblies. By passing the substrate through the air–water interface repeatedly, subsequent layers of molecules can be added to the initial film. A wide range of specialized transfer methods has been developed to control the orientation of layers with respect to one another and to prepare alternating layered films. The easiest multilayers to prepare (and hence most common) are those in which the orientation of the headgroup relative to the substrate alternates in each layer of the film (the Y-type). In principle, by varying the orientation of the headgroups within each layer and/or the surfactant composition within each layer, a wide variety of LB films can be prepared (Figure 2).

In addition to the relative ease of preparation of multilayered films, the primary advantage of LB films involves the flexibility with which the molecular architecture can be tuned. The composition within individual layers and from layer to layer can be precisely controlled by varying the composition of the mixed Langmuir monolayers. The relative spacing between active components (chromophores, redox probes, etc.) in the film can be systematically varied by controlling the adsorbate orientation and by varying the spacer length. Additionally, film deposition is possible on many substrates including both conductors and insulators.

Despite the numerous advantages, LB films have a number of potential disadvantages with regard to electron-transfer studies, including the difficulty of fabricating high-quality films and their fragility in electrochemical experiments. Al-

Figure 2. Examples of Langmuir–Blodgett multilayer assemblies. For simplicity, all surfactants are shown as the same type. Typically mixtures of surfactants are employed; composition can be varied within each layer and/or from layer to layer.

though the compression process results in fewer defects in the Langmuir layer, it can be difficult to optimize the film-transfer process. Inefficient transfer can result in poor film homogeneity and the incorporation of defects in the LB film. Additionally, it can be very difficult to control precise placement of chromophores/redox probes within the film. LB films typically do not withstand electrochemical investigation because they are usually stabilized only by van der Waals interactions and have limited stability unless they are covalently bound to the substrate.

Self-assembled monolayers (SAMs) and multilayers

An alternative to the LB method that eliminates the difficulties of film transfer and results in more stable films depends upon chemical self-assembly of adsorbates directly onto a solid support. In the self-assembly process, molecular assemblies are formed by soaking a substrate in a solution of a surfactant that interacts with the substrate through a reactive headgroup. Strong interactions between the headgroup and the surface drive the saturation of adsorbate binding sites and stabilize the film. Lateral interactions between neighboring adsorbate molecules provide added stability to the assembly and can lead to formation of 2-D crystals if the packing among the adsorbate chains is a reasonable match to the spacing between adsorbate binding sites on the surface.

As early as 1946, Bigelow et al. suggested the use of chemically-modified surfaces produced by self-assembly for applications such as control of wettability, ‘permanent’ lubrication and corrosion prevention [15]. Self-assembly of organic films on metals [16] and metal oxides (e.g., alkyl carboxylates on iron and aluminum oxide surfaces) [17] was extensively investigated; however, highly ordered self-assembled films that form covalent bonds to the substrate were not well known until the 1980s [18, 19]. Nuzzo and Allara’s 1983 report of facile formation of alkanethiol monolayers (from disulfides) on gold surfaces [20] rekindled interest in preparing well-defined molecular assemblies by self-assembly on surfaces.

A number of self-assembled systems have been thoroughly investigated, including organosilicon adsorbates on hydroxylated surfaces such as SiO_2 and Al_2O_3 , carboxylates on Al_2O_3 and organothiol derivatives on the coinage metals. Of these systems, the alkanethiols on gold provide a number of advantages for use in

electron-transfer experiments: They assemble readily to form stable, well-ordered molecular layers, methods for characterizing molecular films on metal surfaces are well developed, and the metallic surface can be used to probe electron transfer electrochemically. They exhibit enhanced solvent and thermal stability and are thus amenable to electrochemical investigation where the electrochemical driving force can be easily varied. Additionally, the effects of the composition of the contacting electrolyte solution can be addressed.

In certain cases, self-assembly methods can be employed to prepare *multilayered* thin films analogous to LB films. Typically, once the surface has been primed with a molecular adhesion layer, subsequent layers are assembled in a layer-by-layer fashion where the end group of the previously deposited layer directs the assembly of the next layer. Strong electrostatic or covalent interactions between the layers serve to stabilize the assemblies. The most notable examples of self-assembled multilayered films are those based upon metal phosphonates [21]. Although these multilayers are structurally analogous to LB films, their thermal and solvent stability makes them potentially more useful in many applications, including electron-transfer studies.

An important, practical advantage of molecular self-assembly is that, given proper adsorbate design, it offers a straightforward and rapid method to form well-ordered molecular films. Facile film formation can be induced with a wide variety of redox probes on the surface of the film. However, successful assembly of the highly ordered mono- or multilayer necessary for electron-transfer studies depends upon the molecular structure of the adsorbate. Careful selection (through design and screening) of the molecular adsorbate is necessary to ensure a well-assembled monolayer possessing a high degree of order and rigidity. The fact that not all adsorbates will form well-ordered assemblies is the major limitation of using self-assembled systems to investigate electron transfer.

5.2.2 Characterization of Molecular Assemblies

Given the dependence of electron transfer on spacer composition, conformation and length in homogeneous systems [5], it is evident that thorough characterization of an assembly's structure and its degree of order is necessary to support the validity of electron-transfer measurements in heterogeneous systems. Improved analytical methods have made it more feasible to determine whether the assemblies have the intended structure and degree of perfection. Even so, detailed characterization is a difficult task that is best met with an array of different analytical tools. In this section we briefly review the analytical methods used for the characterization of ultrathin organic films. A number of useful reviews are available [13, 19, 22, 23]. The material presented here is limited to film characterization that is most relevant to our subsequent discussion of electron-transfer studies. Given the heightened interest in how structure and defects affect electron-transfer measurements, the examples used will come from the more recent studies of self-assembled alkanethiol monolayers on gold. Most of these techniques have been or could be similarly applied to Langmuir–Blodgett film samples. We first consider methods that probe the 'bulk' or average film structure (see Figure 3), followed by methods that are either sensi-

Figure 3. Structure elucidation of *n*-alkanethiol SAMs on gold by techniques excluding diffraction, STM and AFM.

tive to disorder or directly probe defects. Finally, we describe electrochemical studies that reveal defects that may influence (electrochemical) electron-transfer measurements.

Spectroscopic, structural and scanning probe studies

A consistent description of the structure of alkanethiol monolayers on gold has emerged from an array of spectroscopic and diffraction studies. X-ray photoelectron spectroscopic (XPS) studies support the presence of anisotropically chemisorbed alkanethiolates on gold [24–29]. Ellipsometric measurements [24–27, 30], capacitance studies [30] and XPS measurements [31] confirm monolayer film thickness. Fourier transform infrared external reflective spectroscopy (FTIR-ERS) shows that the chains tilt at about 30° off the surface normal, and the plane containing the carbon backbone is twisted out of the plane of tilt by about 50° [25–27, 30, 32, 33].

Diffraction techniques (low-energy electron diffraction [34, 35], helium diffraction [36, 37] and grazing incidence X-ray diffraction [38]), scanning tunneling microscopy (STM) [36, 39, 40] and atomic force microscopy (AFM) [41] served to solidify the conclusions inferred from the less direct spectroscopic methods and provide additional structural details. The sulfur atoms order epitaxially on the substrate in a $(\sqrt{3} \times \sqrt{3})R30^\circ$ structure [36–38, 40, 41]. The angle of the sulfur–carbon bond with respect to the substrate plane is approximately 104° for alkanethiol monolayers [38, 42] and 180° for arylthiol SAMs [42, 43]. Given the agreement between the results obtained from direct structural methods and indirect spectroscopic methods, one

can generally apply an array of complementary spectroscopic techniques with reasonable confidence in characterizing SAMs.

Many of the analytical techniques used to study SAMs provide measures of the average properties of SAMs, i.e., they may not be sensitive to disorder or defects. Contact angle goniometry, FTIR-ERS and electrochemical methods are convenient techniques that provide some information about the degree of order or presence of defects in monolayer assemblies. Contact angle goniometry has been used to probe the degree of order within the top few ångströms of methyl-terminated chains [24–26, 28]. Double-layer capacitance and electrochemical blocking experiments [30] probe the integrity of monolayer films and have shown that, for chain lengths greater than about 10 carbons (in air), the alkanethiol monolayers are close packed and contain few defects. FTIR-ERS studies support these findings and show that the alkyl chains occupy primarily all-*trans* conformations [25–27, 30, 32, 33].

Methods that probe local structure and defects, such as STM and AFM, show that nearly full coverage on the molecular scale is easy to achieve [36, 39, 40]. Defects for long-chain alkanethiol monolayers are restricted primarily to point defects such as missing single adsorbate molecules, grain boundaries between domains and step edges usually related to discontinuities in the substrate [39, 41].

Detecting disorder and defects under electrochemical conditions

To probe the microscopic order of SAMs (here we will treat only nonelectroactive SAMs; those containing tethered redox probes will be discussed later) under the conditions used during electrochemical electron-transfer measurements, functional characterization is performed by cyclic voltammetric techniques. In this subsection, electrochemical blocking effect (*EBE*) and double-layer capacitance (C_{dl}) experiments are detailed. When these experiments are carried out using a structural probe of molecular scale [30, 44, 45], they provide the greatest sensitivity to defects because the effects of defects and disorder dominate the electrochemical response.

If a defect-free molecular assembly covers an electrode surface completely, the assembly is an efficient electrochemical blocker [23, 30, 46, 47]. Electron transfer through the SAM to a solution redox probe is substantially slower than the rate of diffusion of the probe to the surface, and the voltammetric response is a quasi-exponential increase in Faradaic current resulting from electron transfer across the chains of the SAM [30, 46]. This type of response qualitatively supports the presence of a monolayer low in defect sites. A more quantitative measure of the *EBE* of a modified electrode is expressed as the percentage of total blocking achieved using a bare electrode as the standard [48]:

$$EBE = \left(1 - \frac{i_{\text{film}}}{i_{\text{bare}}} \right) \times 100 \% \quad (1)$$

A completely blocking electrode would yield an electrochemical blocking effect of 100 %.

If the molecular assembly coating the electrode contains defects greater than the size of the redox probe (but less the ca. 1 µm in diameter) [23], the electrode as-

sembly will function as an array of microelectrodes. The electrochemical response depends upon the size and separation of the defects. If the defects result in widely spaced bare spots, the current is limited by radial diffusion [23, 30, 46] with a hemispherical concentration profile centered on each pinhole [47]. In the cyclic voltammogram, the resulting sigmoidal current response levels off near $E^{o'}$ and remains constant at more extreme potentials [23, 30, 46, 47]. If, on the other hand, the pinholes are spaced closely enough that their concentration profiles overlap, the voltammetry becomes diffusion-limited at high overpotentials. In either case, the *maximum* pinhole area can be estimated [19, 30].

The double-layer capacitance is another useful electrochemical method for probing the integrity of molecular assemblies in contact with electrolyte solutions. If a cyclic voltammogram is recorded in a solution of electrolyte only, a non-Faradaic current results, and the double-layer capacitance, C_{dl} (or differential capacitance), is measured as half the width of the voltammogram charging envelope given by [30, 48]

$$C_{dl} = \frac{i_c - i_a}{2\nu A} \quad (2)$$

In a SAM-modified electrode, the SAM functions as a dielectric, reducing the permeability of the monolayer by electrolyte and decreasing the charging current [23, 30, 48]. However, a thinner film [30, 49], one with a higher dielectric constant (e.g., containing unsaturated carbons [50]), or one which is more permeable to electrolyte (i.e., a more defective SAM), exhibits increased C_{dl} because the resulting electrical double layer is better organized [23, 30, 48]. The double-layer capacitance is, thus, a convenient check of monolayer quality under the conditions of electrochemical electron-transfer measurements.

5.2.3 Measurement of electron-transfer rates

There are two primary methods of investigation of electron-transfer rates: photochemical and electrochemical. In photochemical experiments, a donor–acceptor pair is synthetically introduced into the system, ideally held at a well-defined separation. Photoexcitation of one of the partners provides the driving force for electron transfer. In systems designed to prohibit energy transfer, monitoring the decay (quenching) of the excited state provides a way to follow the electron-transfer reaction. A chief advantage of photochemical experiments is that electrical contact to the sample is not necessary. The main limitation is that the electrochemical driving force can only be varied by incorporation (usually through new synthesis) of different redox probes.

In electrochemical experiments, the molecular assembly is deposited on a conductive electrode surface that acts as one of the ‘redox partners’. The other partner is a redox molecule either tethered to the molecular film or free in solution. In either case, the film ideally provides a well-defined separation between the electrode and the redox probe. The electrode potential is either swept or stepped to increase the driving force for electron transfer. The chief advantage of the electrochemical elec-

tron-transfer experiment is that one can easily tune the thermodynamic driving force for electron transfer by simply varying the electrode potential. This method can only be applied to systems that are stable under electrochemical conditions.

5.3 Fundamental Studies of Electron Transfer in Organized Assemblies

Fundamental studies of electron transfer in substrate-supported, organized assemblies were pioneered by Kuhn, Möbius and others in the 1970s using specifically designed LB films. Experimentalists built upon this foundation over the last two decades but have increasingly focused on the use of LB systems for applications such as photoinduced charge separation rather than fundamental studies due, in part, to some of the experimental limitations of the LB systems. The pursuit of fundamental studies in organized assemblies was rejuvenated in the late 1980s as well-defined alkanethiol monolayers on coinage metals (particularly gold) became the new experimental paradigm. Recently, self-assembled multilayer systems and hybrid, self-assembled monolayer-LB systems have also been investigated. In this section, fundamental studies of electron transfer in LB systems will be reviewed, followed by a more thorough discussion of the recent work in self-assembled systems.

5.3.1 Electron Transfer in Langmuir-Blodgett Systems

The use of LB films for the study of electron transfer is an outgrowth of work aimed at photochemical charge separation [51–53]. In fact, Kuhn had proposed a light-driven electron pump before any details of the photochemical reaction center were available [52]. The LB technique was attractive because of the relative ease of preparing asymmetric bi- and multilayers needed for charge separation. In addition, compared with unsupported bilayers, LB films were more mechanically stable and were thought to eliminate flip-flop, the migration of a surfactant's headgroup from one side of the membrane to the other, which would randomize the position of redox partners in a multilayer assembly. The pioneering work of Kuhn, Möbius and co-workers on electron and energy transfer in engineered LB films has been extensively reviewed [54–57]. Here we will reiterate the key findings and unsolved challenges to lay the foundation for more recent studies of self-assembled systems.

Distance and material dependence

The rate of weakly coupled electron transfer by a tunneling mechanism is expected to decrease exponentially with increasing thickness of the spacer between donor and acceptor (due to the exponential decrease in electronic coupling with increasing separation [7]). Ideally, the thickness of the spacer in an organized assembly is the fully extended length of the spacer molecule. Any imperfections in a film will affect the spacer thickness and, thus, the electron-transfer rate. In properly designed and

Figure 4. Langmuir–Blodgett multilayer systems pioneered by Kuhn and Möbius. Donor and acceptor surfactants are diluted with nontagged surfactants within each layer. The donor–acceptor separation is enforced by the inner layer spacing.

carefully prepared LB systems where it is possible to measure the dependence of the rate on distance accurately, the rate decays exponentially with distance.

Kuhn and Möbius first demonstrated the exponential distance dependence of electron-transfer rates in LB multilayers through fluorescence quenching experiments [56, 58, 59]. The multilayer assemblies were designed to eliminate energy-transfer reactions, yet permit electron transfer. These were composed of cyanine dye donors and viologen acceptors separated by a variable-length, fatty acid interlayer (e.g., Figure 4). Quenching of the cyanine's excited state by the viologen was used to follow the electron-transfer reaction. The electron-transfer distance was varied by adjusting the length of a single fatty acid interlayer spacer from C_{14} to C_{22} . Separation of the donor and acceptor by more than a single long hydrocarbon chain prevents electron transfer and, thus, fluorescence quenching, as expected. Plots of $\log(I/I_0 - 1)$ vs. distance are linear, which is consistent with an electron tunneling mechanism. The quenching rate is independent of temperature, consistent with a tunneling mechanism [58]. Subsequent work by Whitten's group [60] has shown that electron-transfer quenching studies in supported multilayers, containing *trans*-stilbene chromophores and a variety of different quenchers, yields the same linear dependence.

The LB method has been used to generate a number of well-spaced donor–acceptor pairs using surfactants, redox reagents and chromophores. In addition to the distance dependence studies described above, such systems have been used to investigate the effect of the spacer composition on the electronic coupling between the electron-transfer partners. Variation of the electronic nature and thickness of the spacer layer, without altering donor or acceptor layers, made possible the investigation of the material dependence of electron transfer in LB films. A variety of molecular and polymeric [61, 62] materials was investigated with the aim of understanding how the composition of the spacer layer affects the electron-transfer rate. In a number of cases, β , the material-dependent attenuation coefficient [the slope of the $\log(\text{rate})$ vs. distance plot] has been reported. The first systematic study of the material dependence of electron transfer was reported by Whitten's group [63]. For fatty acid spacers they found $\beta = 0.3 \text{ \AA}^{-1}$, consistent with the data obtained earlier in LB systems where β ranged from 0.3 to 0.4 \AA^{-1} [56, 58, 60, 64].

The incorporation of *trans*-stilbene groups into the spacer resulted in a decrease in β ($= 0.2 \text{ \AA}^{-1}$).

Few other systematic studies of β have been completed using LB films. The values obtained for aliphatic spacers are internally consistent but are not in good agreement with values found in organic glasses [65], bridged donor–acceptor systems [66] or self-assembled monolayer studies (see Section 5.3.2) that are typically in the region of 1 \AA^{-1} . The most likely explanation for this discrepancy is that electron transfer at defects increases the rate and decreases β . An exponential distance dependence has been shown in electrochemical experiments performed on self-assembled multilayers of zirconium bisphosphonates where electron transfer was shown to be dominated by defect sites [67]. If the lower β values are due to defects, given the similarity of the β values among the varied systems, the number and density of defects within the samples would have to be similar.

Probes that are most sensitive to defects [scanning probe microscopy (e.g., AFM and STM) and electrochemistry] are difficult to apply to the multilayered LB systems used for electron-transfer experiments. AFM studies are not sensitive to buried defects, and the insulating nature of the films complicates STM studies. These systems typically are unstable under conditions necessary to probe them electrochemically.

Dependence on the driving force

The rate of electron transfer within LB film assemblies depends upon the thermodynamic driving force, dictated by the redox potentials of the partners, just as it does in solution. The heterogeneous nature of LB assemblies introduces the added possibility of field-induced perturbations upon the driving force. Two field-induced effects, electrical double-layer effects at interfaces and the application of external fields, have been investigated. Fujihira's group showed that an internal double-layer effect influenced quenching rates of a ruthenium sensitizer and several ferrocene-based donors [68, 69]. They reported that 'up-hill' (thermodynamically unfavorable based upon solution redox potentials) electron transfer can occur in the LB assemblies under conditions where the electrical double layer acts to increase the driving force for the reaction. Application of an external field was reported to depress or enhance the rate of electron transfer by stabilizing or destabilizing radical ion pairs generated upon electron transfer [70] in LB films [71, 72].

5.3.2 Electron Transfer in Self-assembled Systems

As discussed earlier, SAMs of alkanethiols on gold surfaces offer access to highly ordered, surface-confined molecular structures. The use of these assemblies as stable, well-defined spacers for studies of electron transfer between the gold electrode and redox centers attached to the film surface [50, 73–83] or in solution [44, 46, 84] is depicted in Figure 5. The densely packed monolayer maintains a precise separation between a gold electrode surface and the pendant or dissolved redox center, and effectively eliminates conformational mobility that can complicate electron-transfer rate studies [73]. An advantage of using electrode-confined spacers is that

Figure 5. Self-assembled monolayers as rigid electrochemical spacers. Close packing of the SAM enforces a precise distance between the redox probes and the electrode. (A) In a tethered redox probe system, the probes are covalently attached to the outer surface of the monolayer. The probes may be undiluted (a probe attached to each chain in the monolayer) or mixed (probe-modified chains are diluted with nonelectroactive chains). (B) In a soluble redox probe system, the monolayer typically contains a single component that provides a well-defined separation between the soluble probe and the electrode surface.

the driving force is infinitely tunable. Systematic variation of the molecular composition of the spacer is not limited to rigid linkers because full extension of the spacer is enforced by the monolayer [84]. However, the degree of order possible will depend upon the type and degree of substitution.

The advantages and challenges of using SAM models for the study of electron transfer in heterogeneous systems were defined in the early work by Weaver's group. They employed self-assembled monolayers to study the electroreduction of adsorbed $\text{Co}^{\text{III}}(\text{NH}_3)_5\text{L}$, where L is a thiophene-based headgroup containing a variable hydrocarbon linker. A large decrease in k_{et} is observed upon incorporation of saturated carbons (System 1) between the thiophene 'lead-in' and the carboxylate, whereas k_{et} is not decreased upon replacement of the saturated hydrocarbons with conjugated hydrocarbons (System 2). However, the monolayers were not structurally well enough defined to ascertain the quantitative dependence of k_{et} upon the degree of saturation or the length of the bridge [85]. An estimate of β ($= 1.45 \text{ \AA}^{-1}$) was obtained in a nonhomologous series of sulfides and disulfides containing 1–5 carbons [86]. Although the bond connectivities were known, the structures within the monolayer had not been determined. Thus, these studies illustrate the potential that SAMs offer as model systems and underscore the need for developing self-assembling systems that yield well-defined molecular assemblies.

This section describes the evolution of the systems and techniques that have made possible detailed studies in which electron transfer has been investigated using self-assembled monolayers. After a brief presentation of the important electrochemical methods for assessing the quality of the electroactive SAMs and determining k_{et} across monolayer spacers, studies of electron transfer across SAMs are presented.

Electrochemical characterization of SAMs containing tethered redox probes

The importance of a well-defined, well-ordered organic film for reliable extraction of electron-transfer kinetics was discussed earlier. The methods of characterizing nonelectroactive SAMs were also presented. In this section, we address methods for assessment of the ideality of assemblies containing pendant redox probes (so-called electroactive SAMs) and strategies for optimizing the electron-transfer characteristics of these assemblies. When a tethered redox probe is used, it is typically incorporated into the film as the minor component, the major component being a nonelectroactive diluent adsorbate. In the ideal situation, the redox probes are well separated from one another and each is surrounded by a well-ordered monolayer of diluent. The ideality of the redox probe response is best determined electrochemically. Four major assessments are available by cyclic voltammetry, including measurement of (1) the charging current at the uncharged surface, (2) the degree of electrochemical blocking of the assembly, (3) the density of redox probe and (4) the ideality of the Nernstian response of the redox probe. Chronoamperometry is often used to measure electrode kinetics, as extraction of the kinetic data is more straightforward by this technique.

If the redox probe has an accessible uncharged state, then cyclic voltammograms may be measured *at potentials where the film surface is neutral* to check whether the capacitive charging matches that of the corresponding nonelectroactive SAM [74]. An increase in capacitive charging is evidence that the electroactive SAM is significantly disordered.

Mediation of electron transfer between a dissolved redox probe and the electrode by surface-confined redox groups has also been used to assess the integrity of electroactive monolayer assemblies. As an example, the reduction of $\text{Ru}^{\text{III}}(\text{NH}_3)_6$, normally occurring at about 0.1 V vs. Ag/AgCl, is fully blocked by an assembly containing tethered *N*-ethylviologen redox probes. However, at the observed reduction potential of the viologen probes (ca. -0.4 V), these probes mediate the reduction of $\text{Ru}^{\text{III}}(\text{NH}_3)_6$ [87]. Similarly, the delayed oxidation of $\text{Fe}^{\text{II}}(\text{CN})_6$ at

SAMs containing tethered ferrocenecarboxamide probes has been cited as an indication that through-chain electron transfer is preferred over electron transfer at defects [88].

The density of tethered redox probe at the surface is another useful parameter in electroactive assembly characterization. The amount of redox probe corresponds to the Faradaic charge of the redox process and is measured from the voltammogram using the area $i_F E$ under the voltammetric wave. The area is readily converted to the redox probe density (Γ , in mol cm^{-2}) [47]. For well-ordered *n*-alkanethiol SAMs, the total (electroactive plus diluent) surface density is one molecule of adsorbate per $\sim 20 \text{ \AA}^2$, or about $8 \times 10^{-10} \text{ mol cm}^{-2}$ [38]. To minimize disorder and electrochemical communication between tethered redox probes, the amount of redox probe should not exceed 10–20 % of the total adsorbate [23].

Assessment of the Nernstian behavior of the redox probe [47] is the most direct measure [23] of the reliability of information from a surface-confined electron-transfer experiment. For SAMs containing tethered redox probes, ideal Nernstian behavior is demonstrated by single voltammetric peaks with full widths at half maxima (FWHM) near $90.6/n \text{ mV}$ at room temperature. This ideal behavior strongly suggests that only a single, reversible redox process is occurring. Factors leading to increased FWHM include a number of processes such as aggregation of redox probes at the SAM surface, differential solvation of redox probe in the electrolyte and presence of redox probes at defect sites [82]. In addition to ideal peak shapes and widths, peak splittings ΔE_p are expected to be near 0 mV at slow scan rates [73–75, 79, 81] for a well-behaved system.

Chronoamperometry is more sensitive than cyclic voltammetry to defects in the SAM and serves as a stringent test of electroactive SAM order and integrity [73, 89]. The linearity of the appropriate plot (e.g., $\ln i$ versus t for a one-electron process) confirms that a single electrochemical process is occurring in the electroactive SAM [23].

It is often possible to optimize the response of a poorly assembled monolayer. In freshly adsorbed mixed SAMs, electroactive adsorbate is always present at defect sites [45, 74]. A distinct advantage of tethered redox probes over freely diffusing analyte is that a nearly perfect SAM is not required [23, 50, 73, 81, 90, 91].

The presence of electroactive adsorbate at defect sites can be reduced to insignificant levels using annealing methods such as the chemical annealing method of Chidsey and Loiacono [45] or the electrochemical annealing method of Finklea et al. [89].

Methods for determining electron-transfer rate constants

Cyclic voltammetric, chronoamperometric and AC impedance spectroscopic (ACIS) methods have typically been used to determine the electron-transfer rates in SAMs. Laviron developed a simple method for determining electron-transfer rate constants by cyclic voltammetry [92]. The method allows the determination of k^0 from the dependence of the cathodic/anodic peak separation, ΔE_p , upon sweep rate, but it is inherently inaccurate because it is based on Butler–Volmer kinetics [78, 93, 94].

Recently, the ability to simulate voltammograms based on the Marcus–DOS equation has allowed the extraction of reliable values of k^0 , νp and λ from CV data by curve fitting [78, 94]. In addition, Bowden and co-workers presented a method for calculating electron-transfer rate constants from voltammograms of electroactive SAMs, which provides a convenient shortcut for electrochemistry which is clearly reversible [93]. The advantages of this approach are that it permits the construction of Tafel plots for $\eta \geq 60$ mV from single voltammograms and that it is less time- and computer memory-intensive than the Murray–Creager method. However, this approach does not yield thermodynamic parameters directly from the voltammograms.

In chronoamperometry, the potential is stepped instantaneously from $E^{o'}$ to a positive or negative overpotential η , resulting in a current spike as oxidation or reduction occurs. The decay of the spike is recorded over time. For a one-electron electron-transfer process, k_η is calculated from chronoamperometry data as the slope of the $\log i$ vs. t plot following a potential step from $E^{o'}$. A Tafel plot is constructed from repeated potential steps. This technique has the advantage of minimizing the time spent at high overpotentials, preserving SAM integrity [23, 76] and allowing more data to be extracted from each sample.

In ACIS, a small-amplitude sine wave is superimposed on a constant potential, and the resulting current is recorded. The current lags behind the alternating potential by a degree proportional to the impedance of the SAM. From a plot of the imaginary versus real parts of the complex impedance, both the capacitance of the SAM and the electron-transfer kinetics can be extracted. Because the bulk of the studies described in this chapter make use of cyclic voltammetric or chronoamperometric methods, ACIS is not discussed further here. Leading references are provided for the interested reader [23, 43, 76].

Fundamental studies of electron transfer across SAMs

In this section, the development of well-defined, self-assembled molecular systems and the key electron-transfer findings are discussed. First, pioneering studies in which fundamental processes in electron transfer across monolayers at metal electrodes are presented. These include electron transfer across well-ordered SAMs using tethered redox probes, freely diffusing redox probes and two juxtaposed electrodes. Next, the effect of changing the chemical environment of the redox probe is examined through a consideration of solvent effects, kinetic heterogeneity and vertical position of the redox probe with respect to the diluent molecules ('buried' versus 'dangling'). Distance dependence and material dependence of electron transfer are then addressed in turn. Finally, several mechanistic studies involving transition-state structures and the effects of ion pairing are summarized.

The development of alkanethiolate monolayers on gold as well-characterized, electrode-bound molecular assemblies sets the stage for electron-transfer measurements in more well-defined systems than has previously been available. Chidsey and co-workers began to adapt and test these systems for studying electron transfer across the monolayer [30, 45, 74]. They chose to employ a pendant ferrocene-carboxylate redox probe. Mixed monolayers were formed of the electroactive redox probes diluted with various amounts of methyl-terminated *n*-alkanethiols (Systems

System 3. Mixed monolayers on gold, $n = 11$ with $m = 9$ and $n = 16$ with $m = 15$.

System 4. Mixed monolayers on gold, $n = 16$ with $m = 15$.

3 and 4). Different combinations of chain lengths for diluent and electroactive adsorbates were used, and the spectrum of mole fractions in the mixed SAMs was investigated.

A number of important conclusions were drawn from this study, as follows. Electrochemical reversibility in electroactive self-assembled monolayers depends upon concentration and polarity of a covalently attached redox probe. Reversible surface electrochemistry is observed for the well-diluted ferrocenyl ester. However, reversibility decreases with steric congestion of redox probe because higher redox probe concentrations lead to disorder due to cross-sectional mismatch of the redox probe and the alkyl chain. Reversibility also decreases with a nonpolar redox probe; the alkylferrocene (System 4) yields broad peaks with long tails positive of $E^{o'}$, consistent with kinetic dispersion of the redox probes and their differential solvation in the SAM.

Chemical annealing steps decrease the surface concentration (Γ) of electroactive species and improve reversibility. Chemical exchange of electroactive with diluent adsorbate appears to take place at domain boundaries and defect sites. A 'domains/defects' model of monolayer structure was presented, whereby two populations of electroactive species are present: one which is fully desorbed after a few days of exposure to a nonelectroactive solution, and the other which remains unaffected by such chemical annealing for at least 10 days.

Based upon the results of this initial work, pendant redox probes appeared to provide two major advantages: (1) By exchanging electroactive adsorbate at defect sites for nonelectroactive adsorbate, electron transfer can be limited to that which occurs across the SAM (where coupling is mediated by the adsorbate chains); (2)

The transient currents (as opposed diffusion-limited currents in the case of freely diffusing redox probes) allow the ready identification of kinetic heterogeneity among the surface-confined redox sites [74].

In a subsequent investigation, Collard and Fox studied mixed electroactive monolayers that had been exchanged with a second electroactive probe, such that two redox tags could be distinguished by CV [95]. Upon exposure to the exchange solution, approximately one-third of the original probe is lost, and the voltammogram peak decreases in width (as had been observed by Chidsey and co-workers). The new electroactive component exhibits a broad peak that can largely be removed in a second exchange with a nonelectroactive thiol without further loss of the original redox species. These experiments confirm Chidsey and co-workers' 'domains/defects' model and provide certainty of control of the environment of electroactive species at the SAM–electrolyte interface [95].

With a structurally well-defined system in hand, Chidsey and co-workers were now able to investigate the relationship between electron transfer and thermodynamic driving force, and to study the activation energy of electron transfer. Using the best-behaved redox probe (System 3) from the previous study [74], k_{et} was measured by CV and chronoamperometry [73]. Single exponential chronoamperometric decays and reversible cyclic voltammograms suggest that a single reversible electrochemical process occurs. Using chronoamperometry, the kinetics were measured at overpotentials from -1.0 to $+0.8$ eV at temperatures from 1 to 47°C . All the k_{et} data were fitted with the Fermi–Dirac modified Marcus equation, which yields the same coupling prefactor ($7 \times 10^4 \text{ s}^{-1} \text{ eV}^{-1}$) at high overpotentials for each temperature. The temperature independence of the coupling prefactor shows that electron transfer across the SAM is nonadiabatic. The standard rate constant k^0 increases approximately twofold for every 15°C increase in temperature. This important report [73] showed that well-defined SAMs could be used to probe systematically the nature of electron-transfer processes in organized heterogeneous molecular assemblies and spurred many subsequent studies in these systems.

Shortly after Chidsey and co-workers' initial papers, Miller et al. reported full characterization of $\text{Au-S}(\text{CH}_2)_n\text{OH}$ monolayers (System 5, $n = 6\text{--}12, 14, 16$) by ellipsometry, XPS and electrochemical methods [44]. The nearly defect-free nature of the monolayers was attributed to hydrogen-bonding interactions between neighboring adsorbate chains at the film–electrolyte interface. The level of defects was probed by varying bridging halides, which should change electron-transfer processes at pinholes from outer to inner sphere. Electrochemical annealing was found to improve the *EBE* [44]. Later, they showed that defects in the SAMs are on the

$\text{HS}(\text{CH}_2)_n\text{OH}$ monolayer precursor

 OR
 Fe^{3+}

} soluble redox probes

System 5. Undiluted monolayers on gold.

nanometer scale or smaller and that the level of defects is sufficiently low as to be undetectable by CV. The passivating effect of 1-octanol upon defect sites decreases sequentially at adsorbate chain lengths longer than hexadecyl, suggesting defect sites account for a greater proportion of the measured current in the cases of shorter chains [96].

Rather than using covalently bonded redox probes, Miller et al. used electroactive species dissolved in the electrolyte (ferricyanide and ferric ion redox probes) to probe electron transfer across the SAMs (Figure 5B and System 5). Owing to the slow electron-transfer rate across the monolayers, the voltammetry was not diffusion limited, so the electron-transfer rates were extracted from the initial portions of the i - E curves. The temperature independence of k_{et} at high overpotentials shows that the electron transfer is nonadiabatic. The observed nonadiabaticity also supports high order. However, reorganization energies from the initial study are low (~ 0.5 eV), possibly due to difficulties in extracting k_{et} from voltammograms containing some contributions from diffusive processes. Qualitative Marcus behavior (the plateau region in Tafel plots) was observed in the initial study [44].

The distance decay constant β (see below) in Miller et al.'s original study was 0.9 per CH_2 , using ferricyanide and iron(III) hexahydrate [44]. In a later study which accounted more thoroughly for double layer effects, λ was determined to be ~ 1 eV for kinetically facile redox probes such as ferricyanide, 1.3 eV for Ru-hexamine and 2.1 eV for iron(III) hexahydrate. With a better understanding of the redox probe behavior, β was found to be 1.08 ± 0.20 per CH_2 and independent of the redox couple and electrode potential [96]. Pre-exponential factors were also extracted from the Tafel plots. The edge-to-edge rate constants (extrapolated) are approximately 10^4 – 10^5 s^{-1} for all redox probes, which is reasonable for outer-sphere electron transfer. The pre-exponential factors are $\sim 5 \times 10^{12}$ s^{-1} [96].

In another study, which extended the understanding of the behavior of both dissolved and tethered redox probes, the electrochemistry of a structurally related series of outer sphere redox complexes was compared at Au- $\text{S}(\text{CH}_2)_{13}\text{OH}$ monolayers (System 5). As bipyridyls replace cyano ligands in $\text{Fe}(\text{bpy})_n(\text{CN})_{6-2n}^{(2n-3)+}$ ($n = 0$ – 3), λ decreases as predicted by Marcus theory. However, the adiabaticity of the redox probe decreases discontinuously upon replacement of the last bipyridyl ligand, suggesting that the ligand hinders the approach of the complex to the film and that electronic coupling is not mediated by these ligands. Similar trends are also observed with methyl- and sulfonate-modified bipyridyl ligands and in $\text{M}(\text{bpy})_3^{3+}$ ($\text{M} = \text{Ru}, \text{Os}$) [97].

Recently, Majda and co-workers developed a new technique for measuring trends in electron-transfer rates through alkanethiol monolayers on mercury by forming mercury–mercury tunnel junctions between two micrometrically-controlled hanging drop mercury electrodes [98]. A SAM is adsorbed on each surface prior to formation of the tunnel junction; asymmetric junctions (with SAMs of different lengths) and voltage biases up to ± 1.5 V are employed. Inverse capacitance increases linearly with chain length, yielding a dielectric constant of 2.7 ± 0.3 . Tunneling currents increase quasi-exponentially with voltage bias. The plot of current versus chain length yields an electron transfer decay constant β of 0.89 ± 0.10 per CH_2 ,

consistent with through-chain coupling. Importantly, β varies only slightly with voltage bias, which is consistent with theoretical prediction for through-bond, but not through-space, electron transfer. Although parallel characterization of the actual molecular assemblies under study is difficult, if not impossible, the method shows promise for routine and direct measurements of electron transfer trends across nonelectroactive alkanethiol spacers without dependence on external redox probes.

Chemical environment of tethered probes: kinetic heterogeneity and solvation sphere

The issues of kinetic heterogeneity (generally related to disorder) and dielectric nature of the solvation sphere are difficult to separate in the experimental arena. Decreasing the polarity of the solvent generally induces disorder in a nonpolar SAM, leading to decreased solvent reorganization energy either through differential solvation of the redox probe by the SAM (resulting in kinetic heterogeneity) or through direct interaction with the nonpolar solvent. Under these conditions, increased k_{et} also may result either from decreased average distance between redox probe and electrode (by virtue of increased disorder) or from decreased λ characteristic of a nonpolar solvent. Because ion pairing and the use of organic solvents are inextricably linked to the issues of kinetic heterogeneity and solvation sphere, all of these topics are addressed together in this section.

Since the first report of electrochemical measurements at SAM-modified electrodes in polypropylene carbonate by Groat and Creager [99], Murray's and Creager's groups have conducted extensive and systematic investigations of kinetic heterogeneity using tethered ferrocene redox probes diluted with methyl-terminated *n*-alkanethiols (analogous to System 3 with $n = 8$, $m = 7$; $n = 16$, $m = 15$; and $n = 18$, $m = 17$ or System 4 with $n = 8$, $m = 7$). Kinetic dispersity naturally makes the goodness of fit to Marcus kinetics suboptimal because a single electron-transfer process is not being considered [78]. The inhomogeneity is apparent from broadened voltammogram peaks and curved chronoamperometric log plots [81]. Analysis of the raw data yields average values for the fitting parameters [78]. The formal potential E^{of} of a redox probe generally moves positively by 60–400 mV upon immobilization at an electrode surface, due to either double-layer effects or destabilization of the positive ion, which is partially solvated by the organic film [23]. The latter effect causes an exaggeration of the average increase in E^{of} when a non-aqueous solvent is used [78]. The inhomogeneity causes analysis of voltammogram wave shapes and Tafel plots to yield artificially low values of λ [81]. However activation studies of diluted ferrocenecarboxyl- and ferrocenyloctanethiol monolayers (analogous to System 3 with $n = 8$, $m = 7$ and System 4 with $n = 8$, $m = 7$, respectively) in chloroethane–butyronitrile at 114–170 K yield a reasonable value of $\lambda = 0.95$ eV [81]. As expected, kinetic dispersion is more important in nonaqueous solvents. Interestingly, the kinetic dispersity is also increased at low temperature [83]. Three models were considered to account for this apparent kinetic dispersion: Gaussian distributions of (1) formal potentials, (2) reorganizational energies and (3) tunneling distances (i.e., electronic coupling parameters) were invoked, and the models were fitted to experimental data by adjusting the independent parameters [82]. The best fit to the broad CV peaks and multicomponent chronoamperometric

System 6. Mixed monolayers on gold, $n = 10-15$.

decays was obtained using the distribution of formal potentials [82]. Such a distribution would be reasonable if kinetically distinct states were 'frozen out' due to decreased thermal energy available for conformational interconversion. Strictly, this would represent not a kinetic dispersion but rather a thermodynamic dispersion of redox sites [82].

Ravenscroft and Finklea conducted extensive studies of ruthenated redox probes tethered to SAMs diluted with $\text{Au-S}(\text{CH}_2)_n\text{COOH}$ (System 6) in a wide range of organic solvents [76]. In nonaqueous media, ion pairing is strong and the monolayers are disordered. Fitting Tafel plots with Marcus theory yielded k^0 and λ . For the more polar solvents, $\lambda_{\text{ox}} = 0.9$ eV and $\lambda_{\text{red}} = 0.7-0.8$ eV. As calculated from the Tafel plots, λ decreases markedly for nonpolar solvents, but later Arrhenius and Tafel studies [100] in acetonitrile yielded a value of $\lambda = 0.8 \pm 0.1$ eV. In agreement with Murray et al.'s studies, the average k_{et} increases by up to an order of magnitude in nonaqueous solvents and does not correlate with solvent relaxation times, implicating SAM disorder as the major factor in the apparent kinetic dispersion in nonaqueous solvents [76].

The effect of solvent choice on ion pairing has been directly addressed by Ingram and Murray, who used tethered redox probes to study the effect of solvent dynamics on electrolyte behavior and the associated interfacial electron transfer [90]. The electron-transfer kinetics of methyl-diluted, tethered ferrocenecarboxylate redox probes (analogous to System 3, with $m = 16$, $n = 15$) were compared in dimethoxyethane (MW = 76) and two polyethers (MW = 400 and 1000). Although electron-transfer activation barriers are nearly constant for the series, k^0 falls off with the increasing molecular weight of the solvent. The change in rate constant was within a factor of two of the change predicted using a solvent dynamics model, indicating that solvent dynamics is responsible for at least part of the kinetic difference. Kinetic dispersion of the redox probes increases in the polymer solvents and at decreased temperature. In DME, k^0 is faster than in perchloric acid, which is consistent with a lower λ expected for the less polar solvent [90].

The relationship between ion pairing and steric congestion of the redox probes has been addressed in separate studies by Buttry's and Mirkin's groups. Ion pairing can be detected on the voltammetric time-scale if it kinetically limits electron transfer due to steric congestion. Using QCM, Buttry et al. measured chemically

System 8. Mixed monolayers on gold.

reversible, potential-dependent changes in film mass consistent with ion pairing in undiluted, ferrocene-containing SAMs [101] (System 7). Mirkin et al. used SAMs to probe ion pairing by comparing azo-*n*-C₄H₈S-Au with the same redox probe successively diluted with C₂H₅S-Au [102] (System 8). Notably, the extensive characterization shows the undiluted monolayers to be densely packed. Azobenzene reduction is difficult in the SAM but facile in solution, and dilution with ethanethiol or the use of smaller cations results in more facile electron transfer, which is consistent with a kinetic limitation due to ion pairing in the congested films.

The effect of nonpolar solvents on the electrochemical behavior of surface-confined redox groups has also been studied by Geiger et al. Undiluted monolayers containing polynorbornyl spacers between dimethoxynaphthalene redox probes and the electrode were employed (System 9). Thiol, dithiol or disulfide head groups were used to increase SAM stability in nonpolar solvents [103]. Calculated by Laviron's method, the values of k_{et} are an order of magnitude faster than expected for a same-length alkanethiol spacer in an organic solvent [104]. The unexplained difference

System 9. Undiluted monolayers on gold, $n = 0, 1, 2$.

System 10. Undiluted monolayers or mixed monolayers on gold.

may result from possible structural disorder in the polynorbornyl assemblies, lack of dilution of the surface-confined redox probe with nonelectroactive adsorbate or possible differences in the material dependence of electron transfer between norbornylogous and *n*-alkyl linkers [105–107]. A relevant comparison is provided by the well-characterized ruthenated staffane monolayers (System 10) of Bard and co-workers, which provide reversible electrochemistry when well diluted with electroinactive *n*-alkanethiols. Like the polynorbornyl linkers, the undiluted staffane SAMs exhibit broad voltammetric peaks attributable to ion pairing and kinetic heterogeneity in organic solvents [108].

As a final note concerning solvent effects, amphiphilic alcohols added to hydrophobic electroactive *n*-alkanethiol SAMs in aqueous solution appear to aggregate on the monolayer surfaces, decreasing the capacitive envelope and enhancing the barrier properties [109, 110]. However, the formal potentials of the redox couples are shifted positively, and the electrochemical reversibility is decreased. This effect had previously been used by Becka and Miller to determine the pinhole current in the presence of a freely diffusing redox probe (see above) [96].

Effects of the chemical environment of tethered probes

Chidsey et al. first referred to the effect of ‘dangling’ redox probes in his studies of optimal conditions for forming well-ordered electroactive SAMs [74]. In an elegant series of experiments, Finklea and co-workers systematically varied the buried, matched or dangling position of a ruthenated redox probe tethered to SAMs containing an $\text{Au-S}(\text{CH}_2)_n\text{COOH}$ diluent (System 6, $n = 10\text{--}15$) [89]. Voltammograms indicate close-packed monolayers are formed, and the redox probes reside in the aqueous phase in all but the most buried cases. λ agrees with the predicted value of 1.0 eV. Plots of $\ln k^0$ vs. redox tether chain length are linear in all three cases, with $\beta_{\text{matched}} = 0.97 \pm 0.03$ per CH_2 , $\beta_{\text{dangling}} = 0.83 \pm 0.03$ per CH_2 and $\beta_{\text{buried}} = 0.16 \pm 0.02$ per CH_2 . The large value of β for the exposed cases is attributed to a significant contribution of chain–chain coupling between redox and diluent adsorbates to the overall electronic coupling. The slight decrease in β for the exposed cases compared with the matched cases may be due either to the decreased efficiency of coupling through *gauche* defects [111] or to the contribution of

through-chain coupling across the electroactive adsorbate chains. The very low β for the buried cases may be due to ion pairing or dielectric effects.

Distance dependence of electron transfer across SAMs

One of the fundamental parameters early workers desired to investigate in electron transfer across self-assembled monolayers was the dependence of k^0 on the distance between redox probe and electrode. Importantly, the potential dependence of the distance decay constant β directly addresses the nature of the nonadiabatic electron transfer. If β decays sharply with increasing overpotential according to Simmons theory of electron transfer across a square potential barrier [112], electron transfer through a square tunneling barrier is implicated; however, if only a weak dependence of β on the driving force is observed, the mechanism probably contains a large superexchange component (see below) [98, 113].

The results from selected studies in which β has been determined for *n*-alkanethiol self-assembled monolayers are presented in Table 1. The measurements made on

well-defined, well-ordered films yield an average value of $\beta = 1.06 \pm 0.08$. The agreement of experimental results with the *ab initio* calculations of Liang and Newton is notable; $\beta = 1.08$ per CH_2 was determined from the chain length-dependent slope of transfer integrals for anion radicals for *n*-ethyl to *n*-octyl spacers [114]. The independence of β of the redox probe is most dramatically indicated in the study by Hong et al. [115] in which the observed rate constants are slowed by the two-electron/two-proton transfer mechanism of the hydroquinone probe (System 11), but an alkanethiol-like decay constant is obtained.

Extreme values arise in systems that may be significantly disordered owing to the use of short alkyl spacers or undiluted electroactive adsorbate. For example, the distance dependence of k^0 in undiluted ethoxyazobenzenyl–amide-functionalized alkanethiol SAMs (System 12) was studied with two, four and six methylenes in the alkyl spacer [91]. For azobenzene reduction, k^0 (by Laviron's method) falls off exponentially with increasing spacer length, yielding $\beta = 1.3 \pm 0.2$ per CH_2 . However, Γ varies greatly with chain length, and the inverse capacitance plot exhibits a nonzero intercept. These factors, along with Mirkin et al.'s detailed characterization of similar systems [102], suggest that these SAMs are increasingly disordered with decreasing chain length, leading to an artificially high decay constant. It has also been suggested that conformational changes required upon azobenzene reduction are responsible for the larger observed value of β [115]. For the STM study listed in Table 1 the seemingly high value of 1.5 per CH_2 may be due to difficulties in calibrating the tip height. Alternatively, it may be due to the vacuum conditions employed, suggesting that electron transfer across wetted monolayers differs from that for dry monolayers [116].

Material dependence of electron transfer

The value of $\beta \approx 1.1$ per CH_2 (0.9 \AA^{-1}) for all-alkyl spacers has become a benchmark for comparative studies of the material dependence of electron-transfer rates.

The effect of introducing new functionality into a structure comprising otherwise regular repeats is readily appreciated by consideration of the superexchange model of electron transfer [114, 117–121]. In the simplest form, the total nonadiabatic coupling across a molecular spacer is calculated as the product of individual couplings between atoms along the way from donor to acceptor. Successive approximations may be made in which coupling between first-, second- and third-nearest atoms are considered. Thus, single strong or weak couplings each affect the total coupling in a scalar way. Furthermore, a series of favorable couplings, as in the case of a conjugated spacer, increase the overall coupling by the product of the individual enhancements.

Electron transfer across monolayers and bilayers containing several types of variations in the material composition is considered in this subsection. SAMs have been studied that contain alkenes, alkynes, phenyl groups, ethers, carboxyl groups, amides, salt bridges, hydrogen bond links and through-space jumps. The effects of interposing these structural modifications in through-chain electron transfer pathways are discussed here.

All-carbon, conjugated spacers

Miller et al. studied electron transfer across alkanethiol SAMs in which the adsorbates contain single alkene or alkyne bonds positioned in the center of the monolayers (System 13) [84]. Electronic coupling across the monolayers was decreased by each of these modifications. The electronic coupling might have been expected to increase as a result of the smaller band-gap of the conjugated linkers. However, the results are explained in terms of the superexchange model, which suggests that couplings between first-, second- and third-nearest neighbors with dissimilar electronics perturb the overall coupling and dominate over longer range couplings. This picture is supported by *ab initio* calculations of the neutral diradical splitting energies for modified and unmodified alkanes, which predict lower coupling for the modified spacers.

Electron transfer across ferrocene-substituted oligo(phenylene-ethynylene)thiols (System 14) on gold has been studied using the ILIT technique [122] (see above) and electrochemistry [50]. Values of $\beta = 0.57 \pm 0.02$ and 0.36 \AA^{-1} were obtained, respectively. Using the electrochemistry method, k^0 is 350 s^{-1} for the 43 Å, 36-bond, six-unit conjugated spacer, compared with 1.25 s^{-1} for the 23 Å, 18-bond alkanethiol

System 13. Undiluted monolayers on gold.

spacer used in Chidsey's seminal study [73]. The conductivity of single oligo(phenylene-ethynylene)thiols embedded in dodecanethiol monolayers on gold has also been investigated by STM. Groups of conjugated thiols were observed at alkanethiol domain boundaries and gold substrate step edges, but apparently single conjugated thiols were isolated on terraces. The apparent tunneling barrier height is at least twice as high over the conjugated spacers as over the domains in the alkanethiol monolayer, consistent with higher transconductance of the conjugated spacers [123, 124]. Efforts to quantify the transconductance of the phenylene-ethynylene spacers by STM are continuing [116].

Spacers containing covalently linked heteroatoms

In an example of careful structural characterization of internally modified SAMs intended for electron-transfer studies, Miller et al. fully characterized ω -hydroxy- n -alkanethiol SAMs on gold containing buried ether functionalities (System 15) [125]. Analysis of the potential of zero charge yielded values of the tilt and twist of the alkane chains in reasonable agreement with those found by reflective IR spectroscopy. The monolayers were concluded to exhibit crystalline packing due to the narrow ether asymmetric stretch, and the broadened and red-shifted methylene stretches were attributed to breaking of the degeneracy of the methylene dipoles by the internal ether dipole [125]. In subsequent measurements of electron transfer across the SAMs containing buried ether functionalities, electronic coupling was

HS(CH₂)₁₆OH

diluent

System 16. Mixed monolayers on gold.

decreased compared with *n*-alkanethiols of the same length. However, electron transfer across the ethers was significantly faster than for the SAMs containing buried alkenes and alkynes described above, as predicted by the *ab initio* calculations. In the context of superexchange theory, these results suggest that the effect of changing the electronic character of one of the bonds (from σ to π) in the chain perturbs coupling to a greater degree than changing one of the constituent atoms to a heteroatom [84].

Spacers containing amide (peptide) groups

By analogy with proteins, the predictions of Beratan and co-workers [126–128] suggest that electron-transfer spacers containing amide groups should exhibit values of β equal to or slightly less than that of alkanes ($0.6\text{--}0.8\text{ \AA}^{-1}$). Three investigations of electron-transfer rates across amide groups in alkanethiol SAMs are summarized next.

In SAMs of FcC(O)NH-*n*-C₁₅H₃₀S-Au diluted with HO-*n*-C₁₅H₃₀S-Au [94] (System 16), k^0 is 1.9 times faster than expected based on Chidsey's 1991 report [73] using $\beta = 1.07$ per CH₂ [19]. This difference could be due either to disorder in the amide-containing SAM or to the change in composition. The electrochemical responses of these amide-containing monolayers are well behaved, suggesting that the difference is due to variation in composition [94]. Thus, this result implies faster electron transfer through an amide group than a carboxylate moiety or two CH₂ groups.

In support of these findings, Majda et al. also recently published results of electron-transfer studies of amide-based adsorbates (System 17) using the Hg–Hg tunnel junction method [98]. The tunneling currents for the amide-containing bilayers are significantly higher than those for alkanethiol SAMs in the same study. A quantitative interpretation of these data is still awaited.

We have investigated the influence of amide bonds upon electron-transfer kinetics in well-organized assemblies of alkanethiolates possessing 'buried' amide groups within the chain [49, 129, 130]. Electron-transfer data obtained for a ferrocene-

System 17. Undiluted bilayers at a mercury tunnel junction, $n = 9, 11$.

carboxamide redox probe diluted in methyl-terminated chains (System 18) from cyclic voltammetry and analyzed by Bowden et al.'s method [93] yield Tafel plots from which k^0 can be extrapolated. Fitting of the data and one-amide-containing SAMs to the Fermi–Dirac-modified Marcus equation [73] yields reasonable reorganization energies ($\lambda = 0.87$ eV) and coupling prefactors. This value of λ is in close agreement with previously published data and supports the kinetic homogeneity of the system [94]. The standard rate constants and coupling prefactors suggest that $\beta_{\text{amide}} \approx 0.8 \text{ atom}^{-1}$ ($\sim 0.7 \text{ \AA}^{-1}$) for electron transfer across peptide bonds in this model system.

Salt bridges, hydrogen bonds and through-space jumps

Liu et al. used self-assembled monolayers to explore electron transfer across non-covalent linkages. Self-assembly of aminoethanethiol and 4-mercaptoaniline monolayers was followed by LB deposition of azobenzene-containing carboxylic acid overlayers (Systems 19 and 20, respectively) [131]. Consideration of relative acid and base dissociation constants and FTIR-ERS suggest that two different ‘bridges’ are formed in the bilayers: (1) a salt bridge in the case of the 4-mercaptoaniline underlayer and (2) an interface with at least partial hydrogen-bonding character in the case of the aminoethanethiol underlayer. The apparent electron-transfer rate across the ionic bonding bridge is much more rapid than in the ‘hydrogen-bonded’ case. However, differences in molecular packing between these two systems, the different electron-transfer distances through the amine-containing underlayers and the

System 19. Undiluted monolayers on gold.

System 20. Undiluted monolayers on gold.

System 21. Hybrid SAM-LB mixed monolayers on gold.

poorly understood interfacial structures complicate the interpretation of these data. This study highlights the importance of interfacial structure on electron-transfer processes and underscores the need for well-defined models containing hydrogen bonding and ionic bonding links.

McLendon et al. studied the distance dependence of electron transfer in bilayers consisting of alkanethiol monolayers on gold with an overlying mixed LB monolayer of 16-ferrocenylhexadecanoic acid diluted with hexadecanoic acid [132] (System 21). In this system, a nonbonded, 'through-space' jump is required for electron transfer to occur between the ferrocene redox probe and the electrode. As expected, electron-transfer rates measured by CV decay exponentially with monolayer thickness. Interestingly, the rate constants are nearly two orders of magnitude lower than expected for a system with these dimensions if the nonbonding link is assigned the same decay constant as a covalent bond. The magnitude of the rate retardation is partially attributable to factors other than the presence of the through-space jump, such as the buried nature of the redox probe and associated constraints on ion pairing processes. However, these data suggest that electron transfer is much slower across noncovalent than covalent links, in accord with the expectations for chain-to-chain electron transfer [114, 117–121, 126–128].

Majda and co-workers provided an elegant demonstration of through-bond and chain-chain hopping processes as parallel mechanisms for electron transfer across SAMs [46, 133]. In *n*-alkanethiol monolayers formed on hanging drop mercury electrodes, the adsorbate coverage Γ is measured by chronocoulometry of the mercuric thiolate formed upon adsorption. For the as-adsorbed films, geometric con-

siderations show that the adsorbate chains are close packed and oriented perpendicular to the substrate. For $\text{Ru}(\text{NH}_3)_6^{3+}$ reduction at these SAM surfaces, k^0 decays exponentially with increasing chain length, yielding the ‘through-bond’ decay constant reported in Table I. Micrometrically driven changes in the surface area of the monolayer-covered mercury drop lead to directly proportional responses in C_{dl} , demonstrating a linear decrease in SAM thickness consistent with tilted chains and the absence of pinholes and bare spots. The increase in k^0 with increasing electrode area suggests that electron transfer can occur through van der Waals bridges between neighboring chains via a chain-hopping mechanism as well as by through-bond coupling along single chains. Fitting of the data to these parallel mechanisms yields a ‘through-space’ decay constant β_{ts} of 1.31 \AA^{-1} for the less efficient chain-to-chain pathway.

Use of SAMs to study mechanistic details of electron-transfer reactions

In this section, selected studies are presented in which self-assembled monolayers have been used to address topics such as transition-state structures and sequential electron transfer. These studies were selected because they address fundamental mechanistic processes. SAMs have also been used to investigate such basic electrochemical phenomena as the potential profile near an electrode [134, 135], interfacial capacitance [136], the influence of redox [134] or polarizable [137] moieties on double-layer structure and the behavior of ultramicroelectrodes approaching molecular size [138]. These important topics are beyond the scope of this chapter, and the interested reader is directed to the literature for more information.

Nuclear reorganization and transition-state structure

Faulkner et al. performed surface-confined electrochemistry at high pressures to probe the structure of the transition state during the oxidation of a tethered ferrocene probe (analogous to System 4) [139]. In these studies, the ferrocene-containing SAMs on gold were subjected to pressures between 1 and 6000 atm. The pressure dependence of the anodic peak potential reveals a positive volume of activation for oxidation, which is consistent with a solvent reorganization in the transition state, which allows ion complexation. This study demonstrates the importance of structural and environmental effects on surface-confined electron-transfer processes.

Electron transfer mediated by surface redox centers

Mirkin et al. studied the diode-like response of mediated ferrocyanide oxidation which occurs if oxidation potential of the surface-confined redox moieties is higher than that of the dissolved analyte [140]. This effect was previously reported by Uosaki et al. for the case of dissolved ferrous ion and an undiluted $\text{Fc}(\text{CH}_2)_{11}\text{S}-\text{Au}$ electrode [88]. Monolayers of azo-O-*n*- $\text{C}_{10}\text{H}_{20}\text{S}-\text{Au}$ containing 1 % $\text{Fc-trans-azo-O-}n\text{-C}_4\text{H}_8\text{S}-\text{Au}$ (System 22) are close packed according to extensive characterization [140]. Reduction of Fe^{3+} but not oxidation of Fe^{2+} is observed at the modified electrode, as ferricyanide reduction is thermodynamically disfavored, showing that ferrocyanide oxidation is mediated by ferrocenes [102, 141]. The diode-like response

System 22. Mixed monolayers on gold.

ceases upon photochemical isomerization of *cis*- to *trans*-azobenzene, consistent with increased free volume in the monolayer [140]. This study demonstrates the control of electron-transfer processes at SAMs by photochemical control of assembly structure and order.

Electron transfer mediated by buried redox centers

Hong and Mallouk [142] measured mediated electron transfer across 1,2-ethanedithylbis(phosphonate) (EDP) spacers in zirconium-containing thin-film multilayers. Ellipsometry shows a stepwise increase in multilayer thickness per EDP layer, suggesting that the degree of disorder is constant with film thickness. For ferrocyanide oxidation, k_{et} depends logarithmically on thickness, and $\beta = 0.43 \text{ \AA}^{-1}$. The low β is shown to be consistent with an electrochemical response dominated by disorder. However, the study demonstrates the potential to model long-range, mediated electron-transfer processes using sequential self-assembly [142]. Recent extensions and refinements of this approach include the construction of zirconium- and cesium-coordinated multilayers [143] and metalloporphyrin stacks immobilized on electrodes [144]. In an analogous monolayer system, a ferrocene group was synthetically placed midway between a metalloporphyrin chromophore and a thiol headgroup (System 23). Sequential electron transfer between the gold electrode and dissolved methylviologen is facile across the ferrocene-containing monolayer, but no electron transfer occurs if the ferrocene mediator is omitted [145].

5.4 Summary and Outlook

The use of mono- and multilayer molecular assemblies to investigate fundamental aspects of electron-transfer reactions in heterogeneous systems has been the focus of this chapter. We discussed the development, characterization and electron-transfer

System 23. Undiluted monolayers on gold.

studies of well-ordered molecular assemblies on solid supports. The relative merits of Langmuir–Blodgett and self-assembled systems were presented in the context of preparing well-defined electron-transfer models. To obtain reliable data from such systems, careful design, preparation and characterization of the assemblies are required. Thus, methods of characterizing the overall structures and assessing the extent of defects were also summarized. Techniques for measuring electron-transfer kinetics in electrode-bound assemblies were briefly reviewed.

Most of the work described in Section 5.3 involved organothiols monolayers on gold because of the relative ease of assembly of highly ordered and well-characterized assemblies in this system. *The key to collecting reliable electron-transfer data and an on-going challenge in this area is obtaining a well-defined system where all parallel electron-transfer paths are the same.* The studies reviewed in this chapter show that when the system is well defined, it has been possible to investigate, in detail, the effect upon electron transfer of (i) the chemical environment of the redox probe (e.g., the nature of the surrounding monolayer, contacting solvent and extent of ion pairing), (ii) the redox probe–electrode separation, (iii) the chemical composition of the spacer and (iv) the mechanisms of charge transfer across monolayers.

Well-defined electron-transfer systems, such as those described in this chapter, provide a number of opportunities for further fundamental study and development of new applications. Investigation of the mechanisms of electron transfer through new monolayer materials (e.g., those containing π -systems such as conjugated oligomers, charge-transfer salts and nucleic acids [146]) will be of increasing interest because these systems offer the possibility of promoting electron transfer over longer distances. As systems involving these new materials are developed, the efficiency of electron transfer will probably become limited by the ‘interconnect’ between the molecule and the electrode [146], hence there will be opportunities in engineering new attachment and linker functionalities.

There is still much to be learned about controlling the directionality or pathway of electron transfer within well-ordered assemblies despite the long-standing interest in mimicking biological processes such as photosynthesis and oxidative phosphor-

ylation. Thus, new systems designed to control the path of electron transfer through the incorporation of intermediate relay redox centers or through exploitation of lateral electron-transfer events [147] will be increasingly of interest. In addition, systems in which electron transfer can be switched or where the rate can be modulated will be important for both fundamental investigation and applications. We expect that designed electron-transfer paths that can control the timing, direction, rate and distance of electron transfer will be achieved and exploited in such applications as chemical sensing, molecular/nanoelectronics and catalysis.

6 Electron Transfer in Self-organizing Systems of Amphiphiles

James K. Hurst and Rafail F. Khairutdinov

6.1 Introduction

The chemical reactivities exhibited by molecules and ions organized around mesoscopic assemblies are often very different from their reactivities in homogeneous solution. The origins of these differences can be found primarily in (1) the non-homogeneous distributions of reactant concentrations and anisotropic and non-uniform mobilities arising from the simultaneous presence of hydrophilic and hydrophobic microdomains and (2) the influence of local electric fields and conformational restraints intrinsic to the particular supramolecular assembly upon adsorbed or partitioned reactants. In this chapter, we shall consider redox reactions in various microheterogeneous surfactant-based assemblies, including micelles, reversed micelles, vesicles and bilayer membranes. Emphasis will be placed upon principles controlling reactivity, which will be illustrated with selected examples taken from the large literature of experimental systems that have been investigated. No attempt will be made to be encyclopedic in scope; the reader is encouraged to consult the numerous available monographs and reviews for additional information on specific systems [1–3].

6.2 General Attributes of Surfactant Assemblies

Surfactants are amphiphilic compounds that contain hydrophobic segments, generally comprised of long-chain alkyl, acyl and/or aromatic groups, that are covalently linked to hydrophilic polar or ionized segments. When these amphiphilic molecules are dispersed in water, the hydrophilic part is easily solvated, whereas the hydrophobic part resists hydration and seeks to minimize the Gibbs energy of the system by aggregating to exclude water. The thermodynamics of surfactant self-organization

are complex, but the particular structures adopted are a result of the balance the energetics of the 'hydrophobic' effect and hydrophilic surfactant-solute interactions with steric constraints arising from the size and geometric shapes of the polar and nonpolar surfactant domains [4]. Although numerous different structures are possible, including rods, tubules and filamentous structures, dilute aqueous suspensions of surfactant molecules carrying two long alkyl chains generally form membranes and vesicles, which are closed bilayer membranes containing an aqueous core, whereas those carrying a single chain or two short chains (e.g., 6–8 carbons) tend to assemble into structurally simpler micelles characterized by a single aqueous-organic interface.

Surfactants can be classified in terms of their head-group charge as anionic, cationic, zwitterionic (i.e., carrying both positive and negative charges) or nonionic (uncharged, but polar). Several common membrane-forming and micelle-forming surfactants are given in Table 1.

6.2.1 Micelles and Reversed Micelles

Aggregation to form micelles usually occurs over a very narrow concentration range as the total concentration is raised, and is associated with an abrupt change in the turbidity of the solution. The concentration of the surfactant that corresponds to the point at which micelles first form in the solution (critical micelle concentration, cmc) usually decreases with increase in the hydrocarbon chain length. The cmc for sodium dodecyl sulfate (SDS), a 12-carbon anionic surfactant, is 8.1 mM; and the cmc for hexadecyltrimethylammonium bromide [cetyltrimethylammonium bromide (CTAB)], a 16-carbon cationic surfactant, is 0.92 mM. In general, the number of surfactant monomers per micelle, i.e., its aggregation number, can vary from less than 10 to more than 100.

A simplified model for ionic micelles given by Hartley [5] is useful for understanding general features of electron-transfer reactions in micellar suspensions (Figure 1). One should note, however, that this model does not accurately depict the hydrocarbon chain packing within the hydrophobic core, which is thought to be considerably more polar and microheterogeneous than implied by this model [6]. In any event, micelles are roughly spherical with radii that correspond approximately to the extended length of the hydrocarbon chain of the surfactant. The hydrocarbon chains constitute the liquid-like cores of the micelles, whose microviscosities have been estimated as ~ 8 cP from ^{13}C NMR spin-lattice relaxation times [7] (cf. H_2O , for which the viscosity is ~ 1 cP). The Stern layer, whose width is up to a few ångströms, consists of the surfactant head groups and bound counterions. Most of the counterions are dissociated from the micelle, however, and are located in the Gouy-Chapman double layer, whose width is up to several hundred ångströms. The net charge of the Stern layer generates a surface potential that is usually within the range 50–100 mV; this potential diminishes through the Gouy-Chapman layer with increasing distance from the micellar surface. It acts as an electrostatic barrier to the passage of charged ions to and across the micellar surface and promotes spatial separation of oppositely charged reactants and/or products.

Table 1. Chemical structures of some synthetic surfactants.

Micelles are in dynamic equilibrium with their monomer surfactants. Two relaxation processes are related to this equilibrium, a fast one in the microsecond time domain associated with the exchange of individual monomers between the micelles and the bulk aqueous phase and a slower one on millisecond time-scale associated with the complete dissolution of the micelles into monomers [8]. For example, the exit rate for the SDS anion from its micelle is about 10^4 s^{-1} , which is considered to be a diffusion-controlled process [8a]. Nonpolar molecules are usually attracted to the relatively hydrophobic inner core of micelles, whereas ionic reactants and products are either associated with the Stern and Gouy–Chapman layers or repelled from the micelles, depending on the sign of electrostatic interaction. For example, NMR studies show that nonpolar molecules such as benzene and naphthalene are

Figure 1. Schematic representation of the Hartley 'oil drop' model [5] for an anionic micelle.

located in a hydrocarbon-like environment in SDS micelles, whereas pyrenesulfonic acid is located at the micellar surface [9]. Compounds dissolved in micelles are also in dynamic equilibrium with those in the aqueous phase. Two distinct pathways have been identified for interparticle migration of adsorbates in micellar media; one involves desorption to the bulk medium and subsequent readsorption to a different micelle, and the other involves direct intermicellar transfer [10]. Exit rate constants for amphiphilic compounds from micelles can vary widely, depending upon the nature and size of the hydrophobic anchor and head-group charge; for example, they decrease dramatically with increasing alkyl chain lengths through homologous series [8a, 11].

Some surfactants form reversed micelles in hydrophobic solvents containing a small amount of water. In these structures, the water is dispersed as microdroplets surrounded by a shell of polar head groups [12]. When the water/surfactant ratio is less than ~ 12 , most of the water molecules are strongly hydrated to the ions or polar head groups of surfactant molecules, giving the aqueous core a viscosity and polarity very different from that of bulk water [13].

6.2.2 Vesicles and Membranes

When swollen in water, surfactant molecules with two long hydrocarbon chains can form single-compartmented (unilamellar) or multi-compartmented (multilamellar)

Figure 2. Schematic representation in cross-section of a unilamellar vesicle formed by surfactant molecules containing two long-chain *n*-alkyl substituents. Polar head groups of individual surfactants are indicated as circles and the two alkyl 'tails' as jagged lines.

closed bilayer structures; the latter consists of several concentric bilayers separated by aqueous shells. These structures are known generically as vesicles, although vesicles composed of phospholipids and other biologically derived surfactants are specifically referred to as liposomes. Unilamellar vesicles divide the reaction environment into three well-defined regions, i.e., the aqueous core is separated from bulk solvent by a thin continuous hydrophobic membrane that constitutes a barrier to ion and charge movement between the inner and outer aqueous phases [2a]. The structural organization of a unilamellar vesicle is shown in cross-section in Figure 2. The membrane is formed by a tail-to-tail orientation of the individual surfactant units, with the alkyl chains forming the anisotropic hydrocarbon phase. On lowering the temperature, the bilayer undergoes a thermotropic phase transition (T_c) from a relatively disordered liquid crystalline state characterized by alkyl chains in various *gauche* conformational states to a more ordered gel-like state in which the chains are aligned in parallel in all-*trans* configurations [4c, 14]. The vesicle shape is roughly spherical, [14b, 15] with diameters that range in size from hundreds to tens of thousands of ångströms; their actual sizes depend upon the ionic composition of the medium and inclusion of adsorbed solutes.

Multilamellar vesicles can be formed merely by raising the temperature of the lipid in water above a critical value [16]; unilamellar vesicles can be formed by a variety of dispersion techniques, including ultrasonic disruption [17], high-pressure extrusion through filters of uniform porosity [15], injection of solutions of the lipid dissolved in organic solvents into aqueous media [18], or reverse-phase evaporation [19]. As dynamic entities, vesicles are considerably less labile than micelles. Unlike the 'flickering clusters' that describe micelles, which are constantly dispersing and reforming in solution, individual vesicles, once formed, generally persist for periods

ranging from days to weeks, until a time at which they ultimately aggregate and precipitate from solution. Likewise, transverse diffusion of individual surfactant molecules from one bilayer leaflet to the other, termed 'flip-flop', occurs on time-scales ranging from minutes to days [4b, 20].

Analogous to micelles, vesicles can solubilize nonpolar molecules within their hydrocarbon membrane phase and adsorb polar molecules and charged ions at their aqueous-organic interfaces. Interventricular transfer of aromatic compounds appears to involve desorption-readsorption processes that are rate-limited by release of the vesicle-solubilized compound [21]; in cases where the dopant binding is strongly favored by both hydrophobic and head-group interactions, these reactions can be very slow. For example, the asymmetric *N*-methyl-*N'*-hexadecyl-4,4'-bipyridinium dication (hexadecylviologen, $C_{16}MV^{2+}$) binds very strongly to anionic dihexadecyl phosphate (DHP) vesicles [22]; measured exit rate constants are $\sim 4 \times 10^{-4} \text{ s}^{-1}$, corresponding to a $t_{1/2}$ of $\sim 30 \text{ min}$ [23]. These studies also revealed an unusual intervessel exchange mechanism in which a water-soluble tetraanionic zinc porphyrin, [5,10,15,20-tetrakis(4-sulfonatophenyl)porphinato]zinc(II), that strongly ion pairs viologens but is repelled from the DHP interface, functioned to 'chaperone' the $C_{16}MV^{2+}$ ion from vesicle to vesicle, presumably by interacting with the vesicle-bound viologen and thereby increasing its release rate.

The rate of transmembrane diffusion of ions and molecules across a membrane is usually described in terms of a permeability constant (P), defined so that the unitary flux of molecules per unit time (J) across the membrane is $J = P(c_0 - c_i)$, where c_0 and c_i are the concentrations of the permeant species on opposite sides of membrane; correspondingly, P has units of cm s^{-1} . Two theoretical models have been proposed to account for solute permeation of bilayer membranes. The most generally accepted description for polar nonelectrolytes is the solubility-diffusion model [24]. This model treats the membrane as a thin slab of hydrophobic matter embedded in an aqueous environment. To cross the membrane, the permeating particle dissolves in the hydrophobic region of the membrane, diffuses to the opposite interface, and leaves the membrane by redissolving in the second aqueous phase. If the membrane thickness and the diffusion and partition coefficients of the permeating species are known, the permeability coefficient can be calculated. In some cases, the permeabilities of small molecules (water, urea) and ions (proton, potassium ion) calculated from the solubility-diffusion model are much smaller than experimentally observed values. This has led to an alternative model wherein permeation occurs through transient hydrophilic defects, or 'pores', formed by thermal fluctuations of surfactant monomers in the membrane [25].

Permeability coefficients vary widely, from $P \approx 0$ for large, insoluble species to $P \approx 10^{-2} \text{ cm s}^{-1}$ for H_2O permeation through phosphatidylcholine (PC) membranes [24]. The permeabilities of small, nonpolar electrolytes are relatively high and, in a homologous series, are generally proportional to their partition coefficients in nonpolar solvents vs. water [26]. Lipophilic ions, i.e., those with a low charge/size ratio and/or hydrophobic substituents, can also show appreciable permeabilities, but transmembrane diffusion of small, charged ions such as normal electrolytes is exceedingly slow. The series, MV^0 , MV^+ , MV^{2+} [where $MV^{2+} = N,N'$ -dimethyl-4,4'-bipyridinium (methylviologen, etc.)] provides a useful comparison. First-order rate constants for transmembrane diffusion across this series are

1×10^3 , 2×10^{-2} , and $< 5 \times 10^{-7} \text{ s}^{-1}$ [27]. Thus, for each increase in electronic charge, the diffusion rate decreased by a factor of $\sim 5 \times 10^4$.

The effective barrier imposed by the bilayer membrane to movement of highly charged ions, coupled with the intrinsic vesicle stability, allows one to prepare asymmetrically organized vesicle systems in which the ionic composition of the inner aqueous phase is different from that of the bulk external phase, e.g., one phase containing aqueous reductants and the other aqueous oxidants. These 'vectorially' organized assemblies can often be conveniently prepared by forming the vesicles in solutions containing one of the reactants, then removing the external reactant by chromatographic means, followed by addition of the second reactant (or its precursors) to the external phase.

Planar lipid bilayer membranes (BLMs) have structural and dynamic properties that are similar to those of vesicles, although they are considerably more susceptible to irreversible degradation and mechanical disruption. They are generally formed at a small orifice in a cup dividing two bulk solutions; this arrangement has the experimental advantage that both sides of the membrane are readily accessible, allowing easy manipulation of the medium composition on both sides of the membrane, in addition to direct measurement of properties related to transmembrane dynamics, such as membrane conductivities. A schematic diagram illustrating measurement of a hypothetical transmembrane redox process mediated by a lipophilic electron carrier is given in Figure 3.

6.3 Surfactant Assembly Microenvironments

The microenvironment generates a spatially inhomogeneous distribution of reagents within the reaction volume. The local properties of a solubilization site can strongly affect the energetics of solvent-solute interactions and therefore the intrinsic reac-

Figure 3. Schematic diagram of an apparatus for measuring transmembrane oxidation-reduction in a planar bilayer membrane. The mechanism described is simple carrier-mediated electron transport. D = aqueous electron donor; A = aqueous electron acceptor; M = membrane-soluble redox mediator; M^- = corresponding lipophilic anion.

tivity of ions and molecules involved in electron transfer. For bimolecular reactions, the geometry of the system and characteristics of the microenvironment in which the reactants are located also influence their capacity to interact. In this context, important effects include the microphase viscosity, local polarities and electric field gradients that exist at the phase interfaces and/or across the membrane. These factors can drastically alter the kinetics of oxidation–reduction reactions to the point that different elementary steps for a common reaction are often rate-limiting in microheterogeneous systems and in homogeneous solution.

6.3.1 Partitioning of Dopants in Micelles

In cases where migration of solute molecules between micelles occurs mainly via dissociation to the aqueous phase and readsorption [28], the reaction dynamics can be represented by the equation 1

where M_n is a micelle containing n solutes and S_{aq} is a solute in the aqueous phase, k_+ is the second-order rate constant for entry of a solute into a micelle and $(n+1)k_-$ is the first-order rate constant for exit of any one solute from a micelle containing $n+1$ solutes.

Taking into account the equilibrium condition, $d[M_n]/dt = 0$, one easily obtains from the set of equations represented by Eq. 1 that the distribution of solute among the micelles obeys a Poisson law [28], i.e.,

$$\frac{[M_n]}{[M]} = \frac{1}{n!} \bar{n}^n \exp(-\bar{n}) \quad (2)$$

where $[M] = \sum_{n=0}^{\infty} [M_n]$ is the total concentration of micelles and \bar{n} is the average number of solutes contained in a micelle. In many cases, Eq. 2 approximates the experimental data fairly well [29], whereas in other cases binomial or geometric distributions were used to describe solute distributions among micelles [30].

Ions adsorbed on the surface of ionic micelles by Coulombic attraction are thought to migrate between micelles primarily during micellar collisions [31]. If only one solute migrates per collision, the migration dynamics can be described by the equation

and the distribution of solutes will again obey the Poisson law [32]. An alternative mechanism that could lead to redistribution of solutes among micelles is the fusion of two micelles to form a short-lived larger aggregate, followed by the fission of this unstable micelle into two smaller micelles. Assuming that each solute of the fused micelle has an equal probability of being in either fragment following fission, a Poisson distribution was obtained for the solute distribution among micelles [33].

6.3.2 Partitioning of Dopants in Vesicles

When the partition dynamics are rapid, the solute distribution in vesicles will obey the same laws as the distributions in micelles. However, when the transmembrane diffusion time of molecules entrapped within the aqueous vesicle core or incorporated into the hydrocarbon phases exceeds the characteristic time of their chemical transformation in chemical reactions, then their partitioning is set by their initial statistical distribution rather than their migration dynamics. In this case also, a Poisson law is appropriate to approximate their distribution among vesicles. This follows because the volume of the inner aqueous phase generally exceeds 10^6 \AA^3 , and the maximum number of molecules that can be entrapped inside the vesicle is correspondingly large.

A complication apparently unique to the relatively static membranes is the tendency for amphiphilic dopants to aggregate in the membrane bilayer, even forming phase-separated domains in the lateral plane at relatively high dopant levels. This phenomenon is spectacularly demonstrated in Langmuir–Blodgett monolayers, where the extent and morphologies of the separated phases can be manipulated by varying the surface pressure and monitored by epifluorescence microscopy [34]. Irregular distributions of dopants can also occur in bilayer membranes [35]. Aggregation is often inferred in these cases from the kinetics of energy- or electron-transfer processes involving the adsorbate [36]; in several cases, fractal analyses have been successfully applied to describe the aggregate structures giving rise to the nonhomogeneous kinetics [37]. Direct observation of association of viologen radical cations (C_nMV^+) adsorbed on anionic DHP vesicles has been obtained by optical spectroscopy [38]. The monomeric species are blue, with characteristic absorption bands at 605 and 397 nm; upon association, the radical forms purple species whose optical bands are shifted to ~ 552 and ~ 366 nm. Several lines of evidence suggest that when the alkyl chain length exceeds $n = 10$, the alkylviologen can intercalate within the membrane, forming part of the bilayer structure [14a, 22, 38, 39]. In this configuration, lateral phase separation may be particularly favorable (Figure 4). Chemical or photochemical reduction of DHP-bound viologens to the corresponding radical cations gives a mixture of monomeric and multimeric species, with the proportion of multimers increasing with the alkyl chain length [38]. An interesting transverse asymmetry was also noted for MV^+ ; when bound to the external DHP surface, this ion was nearly completely dispersed as the monomer, but on the inner surface it was extensively aggregated [40]. Thus, the curvature of the charged interface (convex vs. concave) may also influence the distribution of the dopant in the lateral plane.

6.3.3 Microviscosities of Surfactant Assemblies

As commonly used, the term *viscosity* refers to isotropic systems of macroscopic dimensions. The term *microviscosity* is often used to describe the corresponding properties of the microphases in micelles, vesicles and membranes, despite the fact that this property can be highly anisotropic in these environments. Although am-

Figure 4. Hypothetical three-state model for binding of $C_{12}MV^{2+}$ in the lateral plane of anionic DHP vesicles. Top left, surface adsorption at the membrane interface; top right, intercalation within the bilayer as monomeric units; bottom, aggregation within the membrane bilayer. The average separation distance of the DHP head groups is 7.5 \AA [14a] and the distance between the quaternary nitrogen atoms of the viologen is $\sim 7.0 \text{ \AA}$.

biguous for this reason, microviscosity can be taken as a measure of the ease with which individual molecules in the assembly move with respect to one another. The microviscosity of surfactant assemblies is usually determined by fluorescence depolarization or magnetic resonance measurements, or by analyzing the kinetics of excimer formation or other diffusion-limited bimolecular reactions. A more useful parameter for kinetic purposes is the diffusion coefficient (D), related to microviscosity (η_m) through the standard Stokes–Einstein equation $D = kT/3\pi r\eta_m$.

In membranes, the motional anisotropies in the lateral plane of the membrane are sufficiently different from diffusion in the transverse plane that the two are separately measured and reported [4b, 20d,e]. Membrane ‘flip-flop’ and transmembrane diffusion of molecules and ions across the bilayer were considered in a previous section. The lateral motion of surfactants and additives inserted into the lipid bilayer can be characterized by the two-dimensional diffusion coefficient (D_l). Lateral diffusion of molecules in the bilayer membrane is often an obligatory step in membrane electron-transfer reactions, e.g., when both reactants are adsorbed at the interface, that can be rate-limiting [41]. Values of D_l have been determined for surfactant monomers and probe molecules dissolved in the membrane bilayer; typical values are given in Table 2. In general, lateral diffusion coefficients of molecules in vesicle

bilayers in their liquid-crystalline phase are about three orders of magnitude less than typical molecular diffusion coefficients in water. In the gel phase, where packing of the surfactant hydrocarbon chains is considerably more ordered, D_l values are further reduced by a factor of 100, reflecting the reduced fluidity of this phase. Numerous studies on oriented planar lipid multilayers have given D_l values that are similar to those of vesicles (Table 2 [41d, 42]). Calculations of D_l by molecular dynamics simulations have given values that are in good agreement with experimentally determined values [43].

Only a few D_l values have been reported for micellar systems. Most of the data have been determined by using NMR relaxation and fluorescence methods; D_l values range between 10^{-5} and 10^{-7} cm² s⁻¹ (Table 2 [44]), intermediate between vesicles and homogeneous solution. Reported values for diffusion coefficients within micelle interiors are very similar to those measured for surface diffusion (Table 2 [45]).

6.3.4 Local Polarity and Electric Field Gradients

Aqueous–organic interfaces

A universal feature of these surfactant-based organized assemblies is that electrical potentials exist at their interfaces. In the case of ionic surfactants, these potentials arise primarily from interfacial ionic gradients (e.g., Figure 1); for neutral and zwitterionic head groups, they are the resultant of aligned dipoles arising from geometries imposed by the anisotropic microphase structure and strongly adsorbed solvent molecules. The surface electrical potential of ionic assemblies can, in principle, be calculated from classical electrostatics for particles of known surface charge density [46]. The electrical potential of a charged surface can also be estimated experimentally by comparing the apparent pK_a shift of pH indicators bound to the surface of the charged surfactant assembly compared to a similarly structured neutral assembly. This pK_a shift (δpK_a) is related to the interfacial potential (Ψ_0) by the equation [47]

$$\Psi_0 = \frac{2.3RT}{F} \delta pK_a \quad (4)$$

The surface potential has also been measured by using EPR spectroscopy to determine the interfacial concentration of amphiphilic spin labels, which accumulate if the electrostatic interaction is attractive and are depleted if it is repulsive [48].

All three methods give similar values of interfacial potentials; typical results for some of micelles and vesicles are listed in Table 3. Also listed are estimates of interfacial dielectric constants (ϵ), determined by comparing the position of absorption bands of solvatochromic indicators in the surfactant assemblies with that of reference 1,4-dioxane–water mixtures with known ϵ values. More generally, luminescence probe analysis [49], thermal lensing [50] and absorption spectroscopy [47, 51] are techniques that have all been utilized to measure local polarities in micelles and vesicles. It is important to note that these methods presume knowledge of the loca-

tion of the probe; in a recent study, kinetic evidence was obtained for migration of an amphiphilic spirooxazine from the hydrocarbon interior of PC liposomes to the interface upon photoisomerization to the open-ring merocyanine form [52]. These studies indicate that subtle structural changes can lead to a relatively dramatic intracellular redistribution of dopants.

Microphase interiors

The solvent sensitivity of the emission spectrum and fluorescence quantum yield of pyrene and its derivatives have been used to sense the polarity of microphase interiors. By these methods, pyrene in SDS micelles is located within a micro-environment less polar than water, but more polar than typical hydrocarbons [53].

Figure 5. (a) Profile of the hydrophobic barrier in a phosphatidylcholine liposome. The circles are measured points based upon the polarity index [54]; the solid line is the dielectric constant as determined with fluorescent probes [55]. (b) Calculated relative free energy for diffusion of CH_4 across a dimyristoylphosphatidylcholine bilayer (adapted from [57h]). In both diagrams, distances are measured from the center of the bilayer.

In PC and 1,2-dipalmitoylphosphatidylcholine (DPPC) liposomes below the phase transition temperature, pyrene senses an environment similar to butanol and propanol, respectively, although above the transition temperatures the environment is less polar [49c].

To determine the shape of the hydrophobic barrier of bilayer membranes, fatty acids and PC molecules spin labeled with nitroxides at various positions along the lipid chains were diffused into vesicles and their solvent-sensitive isotropic ^{14}N coupling constants were measured [54]. Results are plotted in Figure 5 in terms of distance of the probe from the bilayer center. Also shown is the profile of the dielectric constant along the membrane normal evaluated from the fluorescence lifetime distribution of fluorescence probes in PC liposomes [55]. These data correlate well with results from neutron diffraction studies that map the positional distribution of water and lipid moieties along the bilayer normal [56].

Model calculations of interface-solute electrostatic interactions reproduce well the view of microenvironment polarities of micelles and bilayers obtained from experimental data [57]. According to molecular dynamics simulations, at ~ 1.2 nm from a bilayer interface, water has the properties of bulk water. At shorter distances, water movement slows as individual water molecules become attracted to the interface. At the true interface, which is a region containing both H_2O molecules and the surfactant polar head groups, the water molecules are oriented with

the positive ends of their dipoles shifted toward the bilayer center, generating a positive potential slightly within the bilayer [57h, 58]. The resulting relative free-energy profile for bilayer permeation by a simple hydrophobic molecule, CH_4 , is shown in Figure 5.

Transmembrane potentials

In compartmented systems such as vesicles and planar bilayer-divided volumes, uncompensated movement of charge across the membrane, whether by diffusion of a lipophilic ion or electron transport, violates electroneutrality. Consequently, the membrane becomes polarized, with the transmembrane potential that develops opposing further movement of charge. The magnitude of this effect can be calculated by assuming that the membrane acts as a simple capacitor. The actual value obtained is sensitive to the internal dielectric constant assumed; nonetheless, for small unilamellar vesicles, uncompensated transmembrane transfer of as few as 10 charges per vesicle generates a transmembrane potential of several hundred millivolts [2a]. This potential is sufficiently large to block many redox reactions. Thus, a carrier-mediated redox reaction such as that described in Figure 3 will progressively slow and ultimately cease after several cycles unless the membrane can be depolarized by cotransport of a cation with the electron or by counter-transport of an anion. A second point to note about this reaction is that the oxidative half-cycle, i.e., the sequence comprising oxidation of M^- by A, transmembrane diffusion of the uncharged M, and its reduction by D, is electroneutral, and therefore does not contribute or respond to the developing potential. In contrast, the reductive half-cycle, comprising reduction of M by D, transmembrane diffusion of the M^- anion and its reoxidation by A at the opposite membrane interface, is electrogenic, i.e., generates a potential, because it involves uncompensated translocation of a negative charge. Thus, unidirectional carrier-mediated transmembrane oxidation–reduction can be either responsive or unresponsive to existing transmembrane potentials, depending upon whether or not the carriers are charged or uncharged. In contrast, direct transmembrane electron transport is always electrogenic, and therefore tightly coupled to charge-compensating transmembrane diffusion of ions, a condition which can profoundly affect net transmembrane oxidation–reduction rates.

6.4 Electron-transfer Reactions in Micelles

6.4.1 Stabilization of Charge-separated States

As previously noted (Figure 1), a micellar interface generates an electrical double layer with a steep gradient attenuating over a few hundred ångströms. This electrical gradient has been used to retard the facile back electron transfer that often follows photochemical generation of high-energy redox partners in solution, thereby increasing the lifetimes of the charge-separated products. Effective charge separation can be achieved when one of the products is electrostatically attracted to the

micelle or, by virtue of overall reduction in formal charge, partitions favorably into the micellar interior, and the other product ion is electrostatically repelled from the micelle. A second means for micellar stabilization of high-energy photoproducts is through an electron relay system in which various donors or acceptors are partitioned in different regions of the microphase system, e.g., as in the following sequence:

where the electron transfer cascade increases the distance of physical separation of D^+ and A_i^- , significantly retarding back-electron transfer. This strategy mimics principles of biological photosynthesis and is analogous to numerous alternative approaches that utilize, e.g., covalently linked donor-sensitizer complexes and ordered polymeric arrays containing appended redox centers, zeolite-entrapped reagents and ordered organic multilayers and inorganic pillared systems, to achieve physical separation of reactive photogenerated species [1e].

Stabilization via electrostatic interactions and proximity effects

The ability of micelles to enhance photoionization yields of hydrophobic molecules was demonstrated in the early 1970s. Thus, the photoionization yields of pyrene [59], phenothiazine [60] and tetramethylbenzidine [61] cations increased when these molecules were encapsulated in anionic micelles. The effect was attributed to efficient escape of electrons from the geminate charge-separated species formed within the micelle, which is accelerated by the anionic interface. The negative micellar surface imposes an electrostatic barrier between the cations, which remain with the micelle, and the aqueous electron in the bulk water phase, thus increasing the lifetimes of the photoredox products.

The use of micellar surface charge to modulate photochemical reactivity is also illustrated by oxidative quenching of hydrophobic 9-methylantracene fluorescence by the dibromide anion. The cationic CTAB micelle is about 10 times more efficient than the anionic SDS micelle in promoting quenching, an effect that was attributed to electrostatic adsorption of Br_2^- on the surface of the CTAB micelle [62].

Retardation of charge recombination rates by cationic CTAC micelles has been observed in investigations of $Ru(bpy)_3^{2+}$ [63] and [5,10,15,20-tetrakis(*N*-methylpyridinium-4-yl)porphinato]zinc(II) ($ZnTMPyP^{4+}$) [64] photo-oxidation by amphiphilic viologens (C_nMV^{2+}). In this case, the primary photoredox reaction takes place in the bulk solution. The viologen radical cations ($^{\bullet}C_nMV^+$) formed by oxidative quenching of the photoexcited sensitizer ions are considerably more lipophilic than the corresponding dications and, once formed, migrated to the micellar interior. However, the photo-oxidized $Ru(bpy)_3^{3+}$ and $ZnTMPyP^{5+}$ ions were repelled from the micelles by coulombic repulsion, leading to a significant increase (up to 20-fold for $^{\bullet}C_{14}MV^+$) in the photoproduct lifetimes.

Proximity effects arising from confining both reactants to the micellar microphase have also been demonstrated. For example, the efficiency of reductive quenching

Scheme 1.

of photoexcited $Ru(bpy)_3^{2+}$ by *N*-methylphenothiazine (MPH) was strongly increased in the presence of anionic tetradecyltrioxyethylenesulfate micelles [65]. In this case, both photoproducts remained associated with the micelle, resulting in fast back electron transfer. However, charge separation could be stabilized by secondary reactions involving reoxidation of $Ru(bpy)_3^+$ by neutral hydrophobic molecules that, upon reduction to negatively charged species, were sufficiently water-soluble to be ejected from the micelle.

Proximity effects have also been found in radical chain reactions of reactants adsorbed on micelles. $Ru(bpy)_3^{2+}$ -photosensitized *cis* to *trans* isomerization of stilbazolium ions is thought to proceed via intermediate formation of pyridyl radicals generated in the primary photochemical event [66]. The quantum yield of *cis* to *trans* isomerization was $\phi_i = 0.5$ in aqueous solution, whereas ϕ_i was as high as 100 when both $Ru(bpy)_3^{2+}$ and stilbazolium ions were adsorbed on SDS micelles. Calculations indicated that, on average, all the *cis*-stilbazolium molecules within a given micelle could be isomerized by absorption of a single photon. This result suggests operation of a highly efficient intramicellar electron-relay reaction (Scheme 1).

Rapid electron exchange has been directly observed by EPR spectroscopy between amphiphilic *N*-ethyl-*N'*-hexadecyl-4,4'-bipyridinium ($C_{16}C_2V^{2+}$) and the corresponding $\cdot C_{16}C_2V^+$ radical cations in mixed viologen-hexadecyltrimethylammonium cationic micelles [67]. From the measured line broadening of the radical signal in the micelles, the electron exchange rate constant was estimated to be $k \sim 5 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ at room temperature. When incorporated into didodecyltrimethylammonium bromide vesicles, the same viologens exhibited even faster apparent electron exchange where, at dopant mole fractions above 0.2, the averaged EPR radical signal underwent exchange narrowing with increasing amounts of

added dopant [68]. However, these studies did not consider the possibility that lateral phase separation of the viologens in the membrane might be contributing to the rapid exchange rates.

Like reactions in normal micelles, rates of electron transfer in reversed micelles can be controlled by the mutual accessibility of the reactants. Electron-transfer reactions between viologen radical cations ($\cdot C_n MV^+$) and various quinones have been studied in aqueous solution and AOT–isooctane–H₂O reversed micelles [69]. For water-soluble anthraquinonesulfonate ions, the rate constants decreased with increasing length of aliphatic chain of viologens, an effect that was attributed to increasing association of the viologen with the surfactant interface. No electron transfer was observed with dimethylnaphthoquinone which, as a hydrophobic molecule, presumably occupied the bulk solvent. Analogously, the photoionization yield of alkylphenothiazines in AOT–isooctane–H₂O and CTAB–C₄H₉OH–H₂O reversed micelles was observed to decrease with increasing alkyl chain length on the phenothiazine [70]. This effect was interpreted as indicating a greater depth of penetration of the long-chain analogs into the organic phase, with attendant greater difficulty of electron ejection into the aqueous microphase. The rate constant for quenching of the luminescence of Ru(bpy)₃²⁺ and a surfactant analog by viologens was decreased by up to 10-fold in water-in-oil microemulsions compared with water [71]. This effect was attributed to restricted access of the viologens located in the aqueous phase to the interfacially adsorbed Ru(II) complex ions.

Vectorial electron transfer

The ability of micelles to partition reactants has been used to construct integrated photocatalytic systems for chemical syntheses. One such system consists of [5,10,15,20-tetrakis(4-sulfonatophenyl)porphinato]zinc(II) (ZnTPPS⁴⁻) as the sensitizer, quinolinium-3-carboxamide cation (DCA⁺) as an electron-transfer mediator, methyl benzoylformate (MBF) as an acceptor and thiosulfate ion (S₂O₃²⁻) as an electron source vectorially organized around cationic CTAB micelles [72]. The complete system as envisioned is shown schematically in Figure 6; methyl benzoylformate is in the hydrophobic core, the negatively charged photosensitizer adsorbed on the micellar surface and the hydrophilic electron donor and positively charged electron-transfer mediator (DCA⁺) residing primarily in the bulk water. The neutral dihydroquinoline (DHQ) produced by oxidative quenching of the triplet excited porphyrin carries an electron from the micellar surface to the hydrophobic interior. Reoxidation by methyl benzoylformate results in the formation of methyl mandelate (MM) with the DCA⁺ returning to the bulk aqueous phase. The overall reaction is given by the equation

From the reported yields [72], it appears that on average up to nine electron transport cycles/mediator had occurred. Significantly, no reduction of MBF by photo-excited ZnTPPS⁴⁻ was observed in the absence of the CTAB micelles.

Figure 6. Reaction scheme for $ZnTPPS^{4-}$ photosensitized-quinolium (DHQ) ion-mediated reduction of methyl benzoylformate (MBF) to methyl α -hydroxyphenylacetate (MM) in CTAB micelles (adapted from [72]).

Photosensitized vectorial electron transfer from the (morpholine)ethanesulfonate anion (MES^-) to 1,5-anthraquinone disulfonate ($AQDS^{2-}$) mediated by dibutyl (BTDB) or diethyl (BTDE) esters of 2,1,3-benzothiadiazole-4,7-dicarboxylic acid solubilized in CTAB micelles has also been reported [73]. The proposed mechanism of BTDB-mediated electron transfer is shown in Figure 7, where reductive quenching of photoexcited BTDB by interfacially adsorbed MES^- is followed by electron transfer from reduced BTDB to the $AQDS^{2-}$, recycling the sensitizer.

Figure 7. Proposed reaction scheme for BTDB-photosensitized reduction of $AQDS^{2-}$ by MES^- in CTAB micelles (adapted from [73]). BTDB is either BTDB or BTDE (see text for definitions).

6.4.2 Kinetic Analysis of Electron-transfer Reactions in Micelles

Quantitative approaches to describing reactions in micelles differ markedly from treatments of reactions in homogeneous solution primarily because discrete statistical distributions of reactants among the micelles must be used in place of conventional concentrations [74]. Further, the kinetic approach for bimolecular reactions will depend on how the reactants partition between micelles and bulk solution, and where they are located within the microphase region. Distinct microphase environments have been sensed by NMR spectrometry for hydrophobic molecules such as pyrene, cyclohexane and isopropylbenzene, which are thought to lie within a hydrophobic 'core', and less hydrophobic molecules such as nitrobenzene and *N,N*-dimethylaniline, which are preferentially located at the micelle–water interface [75]. Despite these complexities, relatively simple kinetic equations for electron-transfer reactions can be derived for cases where both donors and acceptors are uniformly distributed inside the micelle or on its surface.

Reactions in the interior of spherical micelles

Consider the diffusion-controlled electron transfer reaction $D + A \rightarrow D^+ + A^-$ in a spherical micelle of radius R with donors (D) and acceptors (A) located in the micelle interior. Electron transfer is presumed to require collisional interaction of the reactants. When one of the reactants, e.g., the donor, is immobile and placed at the center of the micelle and N acceptor molecules are initially uniformly distributed throughout the micelle interior, the kinetics of the donor decay are given by the expression [76]

$$\frac{n(t)}{n(0)} = \left\{ \sum_{i=1}^{\infty} H_i \exp\left(-\alpha_i^2 \frac{Dt}{R^2}\right) \right\}^N \quad (6)$$

where

$$H_i = \frac{6\left(\frac{d}{R}\right)^2}{\alpha_i^2 \left[1 - \left(\frac{d}{R}\right)^3\right] \left(\frac{\alpha_i^2}{1 + \alpha_i^2} - \frac{d}{R}\right)}$$

d is sum of the reactants radii, α_i are the positive roots of the equation $\tan[1 - (d/R)]\alpha = \alpha$ and D is the diffusion coefficient of the acceptor. When the observation time is sufficiently large, the kinetics are approximated by the first-order expression

$$\frac{n(t)}{n(0)} = H_1^N \exp(-k_D N t) \quad (7)$$

with the rate constant

$$k_D = \alpha_1^2 \frac{D}{R^2} \quad (8)$$

Monte Carlo calculations have shown that the exponential approximation to the decay kinetics is also valid when both electron donor and acceptors move freely within the micelle [77]. In this case, faster short-time components affect at most the first 15 % of the total decay. Equation 8 predicts that the rate constant of the reaction will decrease gradually with increasing micellar size, and will be only 20 % larger than the reaction in homogeneous solution when $d/R = 0.1$ [78].

To obtain the macroscopic kinetic behavior of an ensemble of micelles, one must average the intramicellar kinetics with a given number of reactants over the occupancy distribution. Assuming that decay kinetics in the individual micelles are exponential with a rate constant k_D for a Poisson distribution of acceptors and that acceptors can enter a micelle with the rate constant k_+ and exit it with the rate constant k_- , one has [79]

$$\frac{n(t)}{n(0)} = \exp\left(-\frac{k_+k_D\bar{N}}{k_- + k_D}t - \frac{k_+k_D^2\bar{N}}{k_-(k_- + k_D)^2}\{1 - \exp[-(k_- + k_D)t]\}\right) \quad (9)$$

Thus, the kinetics of diffusion-controlled bimolecular electron-transfer reactions in the micellar interiors differ from that in the homogeneous solution. Numerous data have shown that Eq. 9 reproduces the dynamics of electron-transfer reactions within micelle interiors [80]. Diffusion coefficients (D) estimated from Eqs. 8 and 9 are very similar to those obtained by independent measurements. For example, Eq. 8 gave $k_D = 7.5 \times 10^7 \text{ s}^{-1}$ for electron transfer from excited pyrene to CH_2I_2 in SDS micelles [79b]. One estimates from Eq. 8, with $R = 20 \text{ \AA}$ and $\alpha_1 = 1.5$ (calculated assuming $d = 7 \text{ \AA}$), a value of $D = 1.3 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$, nearly identical with the experimentally determined value of $D = 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ [45].

Reactions on the surface of spherical micelles

The survival probability $W(z, t)$ of a pair of reactants D and A that can diffuse on a spherical surface satisfies the equation [80]

$$\frac{\partial W(z, t)}{\partial t} = \frac{D_l}{R^2} \frac{\partial}{\partial z} (1 - z^2) \frac{\partial W(z, t)}{\partial z} \quad (10)$$

with $W(z, t = 0) = 1$ and $W(z = -\cos \alpha, t) = 0$ as initial and boundary conditions, respectively. In Eq. 10, $z = -\cos \theta$, where θ is the directed polar angle and α is the directed polar angle when the reactants are in contact with each other. The solution to Eq. 10 is expressed by a sum of exponentials [81]. When N acceptors are present on the surface of the micelle, the survival probability for a given initial configuration of acceptors is given by

Table 4. Examples of diffusion-controlled reactions on micellar surfaces.

Reaction	Micelle	R (Å)	D (10^{-7} cm ² s ⁻¹)	Ref.
$\text{Br}_2^- + \text{Br}_2^- \rightarrow \text{Br}_3^- + \text{Br}^-$	CTAB	13.5	0.8	144
$\text{Ag}_2^+ + \text{Ag}_2^+ \rightarrow \text{Ag}_2 + 2\text{Ag}^+$	SHDTE	28	0.6–1.4	31
$\text{Ru}(\text{bpy})_3^{3+} + \cdot\text{MV}^+ \rightarrow$ $\text{Ru}(\text{bpy})_3^{2+} + \text{MV}^{2+}$	SDS	16	6.0	145
$\text{Rh}^* + \text{DMA} \rightarrow \text{Rh}^- + \text{DMA}^+$	CTAB	22	6.2	82b
$\text{Rh}^* + \text{DMA} \rightarrow \text{Rh}^- + \text{DMA}^+$	DTAB	17	6.0	82b
$\text{Rh}^* + \text{DMA} \rightarrow \text{Rh}^- + \text{DMA}^+$	TTAB	19	5.4	82b

Abbreviations: CTAB = hexadecyltrimethylammonium bromide; SHDTE = sodium hexadecyltrioxyethylene sulfate; SDS = sodium dodecyl sulfate; DTAB = dodecyltrimethylammonium bromide; TTAB = tetradecyltrimethylammonium bromide; bpy = 2,2'-bipyridyl; MV^{2+} = *N,N'*-dimethyl-4,4'-bipyridinium; Rh = octadecylrhodamine; DMA = *N,N*-dimethylaniline.

$$W(z_1 \dots z_N, t) = \prod_{i=1}^N W(z_i, t) \quad (11)$$

Finally, the ensemble-averaged quantity $\langle W(z_1 \dots z_N, t) \rangle_N$ gives the probability of donors surviving to time t . Monte Carlo calculations have shown that in many cases the pair survival probability is approximated well by a single exponential except at very short times [79a, 81]. The rate constant k_D is related to the geometric and diffusional characteristics of the system by the equation [79a]

$$k_D = \frac{D_l}{R^2} \left[\frac{2}{1 - (d/2R)^2} \ln \frac{2R}{d} - 1 \right]^{-1} \quad (12)$$

Experimental studies of electron-transfer reactions occurring on the surface of micelles confirm the exponential character of the kinetics; results from some of these studies are summarized in Table 4. The values of the surface diffusion coefficients estimated from Eq. 12 using the measured rate constants are close to values determined by using NMR relaxation and fluorescence measurements [44].

Recent theoretical developments have been directed at incorporating the distance dependence of electron-transfer rate constants into the kinetic equations for diffusion-controlled reactions on the micelle surface, rather than assuming that these are collisional processes [82]. Both forward and back electron-electron transfers have been considered, with fitting of experimental data by numerical integration of appropriate differential equations. A standard Marcus-type expression was used to describe the electron-transfer rate constants. In the particular case of electron transfer from a donor to a single acceptor located initially at θ , one has instead of Eq. 10 [82c]

$$\frac{\partial W(z, t)}{\partial t} = \frac{D_l}{R^2} \frac{\partial}{\partial z} (1 - z^2) \frac{\partial W(z, t)}{\partial z} - k_f(z) W(z, t) \quad (13)$$

with $W(z, t = 0) = 1$ and

$$2\pi R^2 \sin \theta D_l \frac{\partial}{\partial \theta} W(z, t) \Big|_{\theta=\alpha} = 0$$

as initial and boundary conditions, respectively. The rate constant $k_f(z)$ is determined by the Marcus equation [83]:

$$k_f(z) = \frac{2\pi}{\hbar} J^2 \exp(-2r/a) \frac{1}{\sqrt{4\pi\lambda k_B T}} \exp \left[-\frac{(\Delta G_f + \lambda)^2}{4\lambda k_B T} \right] \quad (14)$$

where J denotes the electronic coupling at the donor–acceptor contact distance ($\theta = \alpha$), r is the distance between the donor and acceptor, a determines the distance dependence of k_f , ΔG_f is the reaction driving force and λ is the solvent reorganization energy.

An example of the goodness-of-fit attainable with these equations is given in Figure 8, where the decay kinetics for electron transfer from *N,N*-dimethylaniline to photoexcited octadecylrhodamine on the surface of CTAB micelles is compared with the theoretical fits for two different concentrations of the donor [82b]. The theoretical decay curves were obtained by numerical integration of Eq. 13, followed by ensemble averaging over the Poisson distribution of donors within the micelles; an exponential factor was also added to account for the spontaneous decay of the excited molecules. The parameters ΔG_f and λ were calculated by assuming that the donor and acceptor molecules are on the surface of a sphere of low dielectric

Figure 8. Fluorescence decay curves for octadecylrhodamine B and two concentrations of *N,N*-dimethylaniline on the surface of CTAB micelles. Also plotted as dashed lines are theoretical fits using Eqs. 13 and 14 with the parameters $J = 2 \times 10^{12} \text{ s}^{-1}$, $a = 1.0 \text{ \AA}$, $D = 6.2 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ and $\lambda = 0.93 \text{ eV}$, which are not visible because they reproduce the experimental data within the uncertainty of the linewidth. Adapted from [82b].

constant surrounded by a continuum at the higher dielectric constant of water. As seen from Figure 8, the fits are essentially indistinguishable from the data. For three alkyltrimethylammonium bromide micelles (tetradecyltrimethylammonium bromide, DTAB and CTAB) the overall electron-transfer rate was found to increase with increasing alkyl chain length. This result was attributed to a corresponding decrease in solvent reorganization energies, possibly due to varying extents of water penetration into the head-group regions [82b,d].

The transition from spherical to rod-like micelles changes the dimensionality of the diffusion space and affects the reaction dynamics [84]. The decay kinetics were predicted to follow approximate biphasic first-order kinetics, with the separate components corresponding to the two characteristic micelle dimensions. This behavior has been verified experimentally [85].

6.5 Electron-transfer Reactions in Vesicles and Membranes

6.5.1 Biological Electron Transport and ‘Artificial Photosynthesis’

Szent-Gyorgy first suggested 60 years ago that electron-transfer reactions across a biological membrane are responsible for many biological processes [86]. Since that time, thousands of publications have been devoted to various aspects of electron transfer in living cells, and the central role of electron transport in energy transduction via membrane polarization has been firmly established. Two distinct mechanisms have been delineated, one typified by photosynthetic systems that involves electrogenic vectorial transmembrane electron transfer occurring in a series of short hops between redox components embedded within a membrane-spanning multi-subunit protein complex [87], and the other typified by the mitochondrial terminal respiratory oxidase that involves electrogenic vectorial mechanical pumping of protons or other ions across the bilayer driven by redox-induced protein conformational changes [88]. In photosynthetic reaction centers, the highly organized, precisely defined spatial and energetic relationships of the membrane redox centers create a supramolecular device of incredible efficiency and photostability. The desire to duplicate these properties in simpler devices for practical applications associated with solar energy photoconversion and storage has spawned an area of research known as ‘artificial photosynthesis’. Indeed, spectacular achievements have recently been reported in constructing a liposomal membrane-based organized assembly utilizing a donor–sensitizer–acceptor molecular triad as a vectorially organized electron-transport chain. When a quinone pool was included in the membrane, photoexcitation of the sensitizer generated a proton electrochemical gradient [89] of sufficient magnitude to drive ATP synthesis by a membrane-incorporated F_0F_1 -ATP synthase [90], analogous to related processes in natural photosynthetic systems. However, in simple artificial systems devoted to high-flux applications such as photogeneration of fuels, it now appears that the most efficient systems will incorporate distinctly nonbiological redox processes in their design. For example, it

appears much more efficient in simple self-assembling arrays to initiate or stabilize charge separation in photoredox reactions across the membrane interface, rather than within the membrane plane, and to use electroneutral carriers to effect trans-membrane oxidation–reduction, rather than electrogenic processes such as trans-membrane electron transport.

6.5.2 Primary Charge Separation Events

As with micelles, vesicles can dramatically influence reaction dynamics by favorably partitioning the reactants in different microphase domains. One striking example is the oxidative quenching of photoexcited water-soluble zinc porphyrins by viologens. In homogeneous solutions containing electron donors, net quantum yields for photoreduction of C_nMV^{2+} dications to the corresponding $^{\bullet}C_nMV^+$ radical cations by triplet-excited $ZnTPPS^{4-}$ is low and concentration dependent because the sensitizer and electron acceptor tend to ion pair, forming a $ZnTPPS^{4-}-C_nMV^{2+}$ complex that undergoes static quenching [91]. However, in suspensions of anionic DHP vesicles, the C_nMV^{2+} is preferentially adsorbed at the vesicle interface and oxidative quenching occurs with near-unity quantum yields [92]. The quenching rate constants for the reactions of strongly adsorbed C_nMV^{2+} ions were only $\sim 10^7 M^{-1} s^{-1}$, which is about 100 times lower than bimolecular quenching in homogeneous solution. From the ionic strength dependence of this reaction, as well as chemical reduction of DHP vesicle-bound C_nMV^{2+} by $S_2O_4^{2-}$ [39a], the effective surface charges of the bound viologens were estimated to be -10 to -12 esu. Thus, the reactions are probably still nearly diffusion-controlled, with the reduced quenching rates arising from exclusion of $^3ZnTPPS^{4-}$ from the anionic vesicle interface in the vicinity of the bound viologen. One might note that the reaction is efficient only because the zinc porphyrin triplet lifetime is exceptionally long, i.e., of the order of milliseconds [93]. The use of several anionic sensitizers with excited state lifetimes in the microsecond range gave very inefficient formation of photo-products when reacted with DHP vesicle-bound C_nMV^{2+} ions [92]. Co-adsorption of the nominally water-soluble $ZnTMPyP^{4+}$ {[5,10,15,20-tetrakis(*N*-methylpyridinium-4-yl)porphinato]zinc(II)} ion also gave inefficient photoreduction of the bound viologens [36b]. Decay of $^3ZnTMPyP^{4+}$ was complex, and exhibited apparent triphasic behavior suggesting that aggregation had occurred. The low quantum yields were attributed to efficient triplet–triplet annihilation, charge recombination and other dissipative cross-reactions that increased when the reactants were confined in close proximity on the vesicle surface. In the $ZnTPPS^{4-}$ -photosensitized reaction, charge recombination was very slow, with decay half-times on the tens of milliseconds time-scales, an effect which can also be attributed to electrostatic repulsion, in this case between the lipophilic vesicle-bound $^{\bullet}C_nMV^+$ radical cation and the anionic $^{\bullet}ZnTPPS^{3-}$ π -cation radical.

Similar behavior has been reported for electron transfer between photoexcited [(trimethylammonio)propyl]thiadicyanobocyanine (TTDC $^{3+}$) and triphenylbenzylborate (TPBB $^-$) anions [94]. In aqueous solution, photoinduced charge separation was strongly attenuated by complex formation between the sensitizer and reducing

agent, but in the presence of DPPC, DOPC and L- α -dioleoylphosphatidic acid liposomes, reaction was facilitated by preferential localization of the lipophilic TPBB⁻ ion within the membrane interior, with adsorption of TTDC³⁺ occurring within the interfacial head-group region of the bilayer. These environments facilitate electron transfer since the net electrostatic charge is removed from the ion in the membrane interior and also decreased in the interfacial region. The electron-transfer efficiency for membranes in their gel phases was higher than in their liquid crystalline phases, possibly because the TPBB⁻ was excluded from the more ordered interior, thereby decreasing the donor-acceptor distance.

Comparative studies have also been made of the kinetics of electron transfer from photoexcited ³ZnTPPS⁴⁻ and ³ZnTMPyP⁴⁺ ions to DHP vesicle-bound *N*-alkyl-4-cyanopyridinium (C_{*n*}CP⁺) ions [95]. In homogeneous solution, oxidative quenching of these sensitizers obeyed simple exponential rate laws whose rate constants (*k_q*) were insensitive to the *N*-alkyl chain length of the oxidant. The quenching kinetics remained exponential in the presence of negatively charged DHP vesicles (Figure 9a), although now the *k_q* for ³ZnTPPS⁴⁻ quenching decreased progressively with increasing alkyl chain length through the series of C_{*n*}CP⁺ ions (Figure 9b). In contrast, *k_q* for the ³ZnTMPyP⁴⁺ ion increased progressively with increasing chain length (Figure 9b). The charge recombination rate constant for both zinc porphyrin π -cations decreased progressively with increasing chain length on the \cdot C_{*n*}CP radicals.

The chain length dependences of *k_q* are in quantitative accord with a dynamic model wherein the relative rate constants were determined by C_{*n*}CP⁺ partitioning between the aqueous phase and the aqueous-membrane interface, with only the aqueous-phase component being reactive toward ³ZnTPPS⁴⁻ and only the surface-bound component being reactive toward ³ZnTMPyP⁴⁺. The absence of ³ZnTPPS⁴⁻ quenching by DHP vesicle-bound C_{*n*}CP⁺ was attributed to strong repulsion between ³ZnTPPS⁴⁻ and negatively charged vesicle surface. The absence of appreciable reaction between DHP vesicle-bound ³ZnTMPyP⁴⁺ and C_{*n*}CP⁺ located in the aqueous phase was attributed to the fact that reduction of C_{*n*}CP⁺ is energetically more favorable when at the less polar membrane-water interface than in the bulk aqueous phase. The reduction in charge recombination rates with increasing chain length was rationalized in terms of the increasing hydrophobicity of the radical product. For the reaction with \cdot ZnTMPyP⁵⁺, this increasing hydrophobicity presumably leads to relocation of the neutral \cdot C_{*n*}CP radical more deeply within the bilayer, resulting in an increased separation distance from the membrane-bound oxidized porphyrin. Reaction with the aqueous \cdot ZnTPPS³⁻ π -ion radical is hindered by the electrostatic barrier provided by the DHP vesicle. In this case, the chain length dependence may arise from partially rate-limiting viologen radical exit rates, which are expected to decrease with increasing length. As in the study with C_{*n*}MV²⁺ ions as oxidative quenchers [36b, 92], net photoproduct yields were considerably higher when ZnTPPS⁴⁻ was used as the photosensitizer, i.e., when electron transfer was driven across the membrane interface, than when both sensitizer and quencher were membrane bound. Typically, quantum yields for the formation of charge-separated photoproducts were ~ 0.7 for ZnTPPS⁴⁻-photosensitized reactions and ~ 0.01 for ZnTMPyP⁴⁺-photosensitized reactions, the dominant factor limiting the latter quantum yield being the large rate constant for charge recombina-

Figure 9. (a) Kinetics of ${}^3\text{ZnTMPyP}^{4+}$ quenching by C_{10}CP^+ in the presence of DHP vesicles. The solid line is the theoretical fit assuming exponential decay with a characteristic time $\tau = 0.9$ ms. (b) Rate constants for ${}^3\text{ZnTPPS}^{4-}$ (open circles) and ${}^3\text{ZnTMPyP}^{4+}$ (solid circles) quenching by C_nCP^+ in DHP vesicle suspensions. Data adapted from [93].

nation on the vesicle surface relative to processes that led to the formation of stable products.

The overall electrostatic charge of the vesicle can also exert more subtle effects on the electron-transfer dynamics of bound reactants. These effects are often complex and difficult to interpret because they can be expected to alter various elementary steps in the overall reaction in opposing ways. This complexity is well illustrated in the systematic study of the influence of the surface charge in mixed DPPC–DHP and DPPC–didodecyldimethylammonium (DDDMA) liposomes on photoinduced electron-transfer reactions involving chlorophyll and several electron acceptors [96]. The impetus for these studies was to find ways to increase the low efficiencies of photoinduced charge separation and the lifetimes of the immediate redox products, conditions that were inherent to binding of the sensitizer to the vesicles. Adding anionic or cationic surfactants had numerous effects, which could include altering the extent of quenching of the excited chlorophyll molecule, the yield of radicals formed by oxidative quenching and the rates of charge recombination. These effects

Scheme 2.

were modulated by the salt composition and ionic strength of the medium, and could be duplicated upon replacing the DHP or DDDMA with other charged surfactants. Thus, it appears that they were attributable primarily to the magnitude of the surface charge on the vesicle. A self-consistent rationalization of the observations could be made by assuming the reaction scheme shown in Scheme 2, where the oxidative quencher is a quinone (Q).

Reaction 1 represents formation of the geminate reaction products [the chlorophyll π -cation radical ($\cdot\text{Chl}^+$) and quinone radical anion ($\cdot\text{Q}^-$)] within the bilayer by electron-transfer quenching of the photoexcited chlorophyll triplet state; reaction 2 represents separation of the radical products by diffusion from the cage; reaction 3 represents charge recombination of the dissociated products; and reaction 4 represents geminate recombination within the cage resulting in no observable product formation. In many systems, step 3 was biphasic; this biphasic character was attributed to $\cdot\text{Q}^-$ partitioning between two different reaction environments, being either contained within the relatively hydrophilic head-group region of the membrane or expelled to a somewhat ill-defined more aqueous environment in the interface. Because the chlorophyll molecule was relatively strongly anchored within the head-group region of the membrane through its pendant phytol chain, emphasis was placed upon the influence of the surface charge on the mobility and distribution of the $\cdot\text{Q}^-$ ion. In principle, the surface charge can alter the reactivity by affecting any or all of the reaction steps in the scheme. Depending on the orientation of the reactants, the charge could stabilize or destabilize the geminate pair (reactions 1 and 4), promote or hinder cage escape by diffusion of $\cdot\text{Q}^-$ (reaction 2) and alter the distribution of sites occupied by $\cdot\text{Q}^-$, and thereby the overall rate of charge recombination (reaction 3). In practice, it was found for systems containing the membrane-soluble benzoquinone molecule that vesicles containing a negative surface charge gave increased photoproduct yields and increased lifetimes of the charge separated species, whereas vesicles containing a positive surface charge gave the opposite result relative to the uncharged system [96a]. The anionic charge was thought to promote expulsion of $\cdot\text{Q}^-$ from the membrane interior to a surface site relatively remote from $\cdot\text{Chl}^+$, effectively decreasing reactions 3 and 4 and promoting reaction 2. In contrast, the positively charged interface was viewed as providing an attractive interaction that held the $\cdot\text{Q}^-$ radical anion within the membrane plane, and therefore in close proximity to its reaction partner, $\cdot\text{Chl}^+$. This model was also used to rationalize the observed effects of surface charge upon reactions initiated by reaction of ${}^3\text{Chl}$ with water-soluble cationic and anionic quenchers, the most dramatic of which was a large (up to 7-fold) increase in photoproduct yields in anionic vesicles when anionic quinones were used as quenchers. This was attributed to

enhancement of reaction 2 by efficient expulsion of the highly charged $\cdot Q^{2-}$ radical dianion [96b]. An additional interesting observation was that charge effects were greater when the ionic strengths in the inner aqueous core and bulk solvent differed than when the salt compositions were identical [96c]. This effect was suggested to arise from changes in lipid packing, affecting the benzoquinone mobility.

Similar behavior has been reported for the dependence of photoionization yields and tetramethylbenzidine ($\cdot TMB^+$) radical cation lifetimes upon the surface charge of the solubilizing vesicles [97]. Specifically, the photoionization yield (ϕ_i) was found to decrease linearly with decreasing interfacial electric potential (Ψ_0) in negatively charged DHP vesicles. The photoionization process presumably involves electron ejection from photoexcited TMP into the bulk aqueous phase. This dependence mirrored that observed for photoionization of TMB and perylene solubilized in anionic sodium lauryl sulfate micelles [98]. Qualitatively, these effects were attributed primarily to inhibition of the geminate recombination of photogenerated electrons and cations by the negative interfacial potential (analogous to reaction 4 in the above scheme). The rate constant for $\cdot TMB^+$ decay is thought to proceed via interaction with nucleophiles in the bulk phase; in both DHP vesicles and the micellar system, the rate constant was found to decrease logarithmically with increasing negative Ψ_0 , implying that the potential presents an activation barrier to the movement of the nucleophile into the microphase. However, this interpretation was rendered ambiguous by the observation that in cationic dioctadecyldiammonium chloride (DODAC) vesicles, the decay rate was actually slower than in DHP vesicles and was promoted by addition of salt (which reduces the magnitude of the positive Ψ_0). In this case, it was suggested that the dominant effect of the surface potential was to change the intravesicular location of $\cdot TMB^+$, i.e., a positive potential would tend to exclude the cation from the vesicle interface, making accessibility to external nucleophiles more difficult.

The opposite result was obtained in a study of vesicle surface charge effects upon photoionization of ZnTPP [(5,10,15,20-tetraphenyl-21*H*,23*H*-porphinato)zinc(II)] in frozen mixed DPPC–DODAC and DPPC–DHP vesicles [99]. Optical spectroscopic measurements indicated that the zinc porphyrin molecules resided in very similar environments within the polar head-group region of the membrane in all of the vesicles. Photoionization efficiencies increased progressively with increasing mole fraction of the positively charged DODAC surfactant in the mixed vesicles and decreased progressively with addition of increasing amounts of the anionic DHP surfactant. These effects were interpreted as indicating that the negative surface potential generated by DHP hinders escape of the electron from the vesicle and thus from the photogenerated $\cdot ZnTPP^+$ π -cation radical. Correspondingly, addition of the positively charged DODAC molecules creates more favorable electrostatics for the electron to escape from the charge-separated geminate pair through the vesicle interface.

The reasons for the divergent effects of surface charge on TMB and ZnTPP photoionization yields in vesicular suspensions are unknown. Experimentally determined photoionization yields are complex quantities, which include as elementary processes primary ionization cross-section terms, dry electron escape probabilities, relatively complex electron hydration processes and recombination of various hy-

drated forms of the electron with the radical cation. The interfacial potential may affect each of these terms differently for different electron donors, which may further be dependent upon their location within the aggregate microphase.

The direction of electron transfer within the asymmetrically organized membrane can apparently also influence the reaction dynamics. As noted above, reductive quenching of photoexcited TTDC³⁺ by TBPP⁻ was more efficient below than above the membrane phase transition [93]. Given the solubility properties of the reactants, electron transfer almost certainly occurred in the transverse direction, i.e., normal to the plane of the interface. Diffusion-limited charge recombination reactions between pyrene radical anions and *N,N*-diethylaniline (DEA) radical cations formed by photoinduced electron transfer in liposomes exhibit an entirely different dependence upon membrane structure [100]. In this case, the reaction rate increased markedly around the vesicle gel-to-liquid crystalline transition, a region characterized by highly disordered side-chains and relatively low internal viscosity. By using pyrene molecules tethered to polar head groups through methylene chains of varying lengths, it was shown that these reactions were not influenced by the depth of penetration of the chromophore within the membrane bilayer, provided that it was not confined to the interface [101]. Presumably, then, these reactions were isotropic within the hydrocarbon microphase of the membrane and rate-limited primarily by the diffusion of [•]DEA⁺ [101]. In contrast, the transverse vectorial organization photoexcited TTDC³⁺ by TBPP⁻ apparently allows the effective distance between donor and acceptor to change upon undergoing the phase transition such that the increase in electron tunneling efficiency accompanying reduction in the separation distance outweighs the rate retarding effects of the increased microviscosity of the more ordered gel phase.

These examples should serve to underscore the difficulty in predicting the effects that interfacial potentials, membrane structure and microphase organization will have on electron-transfer reactions across the membrane interface and within the bilayer itself. The principles involved are common to micelles and vesicles, but the more anisotropic and highly ordered vesicles provide a more complex reaction environment for solubilized or adsorbed reactants.

6.5.3 Kinetic Analyses

Reactions that occur between components in the bulk solution and vesicle-bound components, i.e., reactions occurring across the membrane interface, can be treated mathematically as if they were bimolecular reactions in homogeneous solution. However, kinetic analyses of reactions on the surface of mesoscopic structures are complicated by the finiteness of the reaction space, which may obviate the use of ordinary equations of chemical kinetics that treat the reaction environment as an infinite surface populated with constant average densities of reactant molecules. As was noted above, the kinetics of electron-transfer reactions on the surface of spherical micelles and vesicles is expressed by a sum of exponentials that can be approximated by a single exponential function only at relatively long times [79a, 81]. At short times, the kinetics of the oxidative quenching of excited molecules on these surfaces are approximated by the equation [102]

Figure 10. Kinetics of fluorescence quenching of OpyPC by HDP^+ in (a) the DOPC monolayer at $P = 30 \text{ mN m}^{-1}$ and (b) DOPC vesicles. The solid lines are theoretical curves calculated from Eq. 15 with $\tau = 115 \text{ ns}$, $R = 1 \text{ nm}$ and (a) $D_l = 5.2 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ and (b) $D_l = 4.1 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ symbols are defined in the text. Adapted from [102b].

$$\frac{n(t)}{n(0)} = \exp\left(-\frac{t}{\tau} - 7.44NR\sqrt{tD_l} - 2.28ND_l t\right) \quad (15)$$

where τ is the fluorescence lifetime in the absence of a quencher, N is the quencher concentration in molecules per unit area, R is the radius of electron transfer from the excited molecule to the quencher and D_l is the lateral diffusion coefficient of the reactants. Typical kinetic data for oxidative quenching of fluorescence are presented in Figure 10 for reaction between photoexcited {10-[6(8)-octadecylpyrenyl]decanoyl}-2-hexanoylphosphatidylcholine (OpyPC) by the 4-(*N*-hexadecylpyridinium-4-yl)-pyridine cation (HDP^+) on the surface of a dioleoylphosphatidylcholine (DOPC) monolayer (a) and DOPC vesicles (b) [102b]. Fits obtained by using Eq. 15 are given as the solid lines, from which the lateral diffusion coefficients of the reacting species can be estimated. In this example, the lateral diffusion coefficient in the monolayer decreased with increasing surface pressure, P , from $D_l = 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ at $P = 6 \text{ mN m}^{-1}$ to $5.2 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ at $P = 30 \text{ mN m}^{-1}$. The diffusion coefficient measured in the monolayer at higher surface pressures is comparable to that estimated for DOPC vesicles, for which $D_l = (4.1\text{--}4.4) \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ [103]. More generally, Monte Carlo simulations based on $\text{H}_2\text{TMPyP}^{4+}$ triplet-triplet annihilation reactions on the surface of anionic DHP vesicles have been compared with more approximate methods commonly used to evaluate surface reactions to test their accuracy [104]. The comparisons indicate that these simpler methods gave

reasonably accurate estimations of D_l for spherical surfaces whose dimensions are equal to or greater than those of small unilamellar vesicles.

6.5.4 Transmembrane Oxidation–Reduction Reactions

Net reaction between hydrophilic oxidants and reductants separated by bilayer membranes has been convincingly demonstrated in numerous asymmetrically organized vesicle and planar bilayer systems [2a–c]. Particularly compelling examples are those in which electrogenic electron transport is accompanied by net translocation of lipophilic cations or anions, as is required to maintain electroneutrality. For example, MV^{2+} occluded within the inner aqueous phase of DHP vesicles can be completely reduced to the $\cdot MV^+$ radical cation by $S_2O_4^{2-}$ ion in the bulk phase, but only if an equal or greater amount of viologen is initially present in the external environment [40]. Neither MV^{2+} nor $S_2O_4^{2-}$ is membrane permeable. The reaction is biphasic, with rapid bimolecular reduction of external MV^{2+} being followed by slow first-order reduction of the internal MV^{2+} . Reduction of each internal MV^{2+} is accompanied by stoichiometric uptake of a single $\cdot MV^+$ radical ion. These events are depicted schematically in Figure 11. Under most conditions, the accumulation of lipophilic $\cdot MV^+$ ion occurs against its concentration gradient, and so its redistribution cannot be attributed to passive diffusion, but is driven by the thermodynamic potential of the redox reaction. This tight coupling between ion translocation and transmembrane oxidation–reduction establishes unequivocally that electron transport has occurred across a closed bilayer membrane.

A more difficult question to pursue is how electron transport occurs [38]. Three types of electron-transport mechanisms across bilayer membranes have been envisioned, including (i) direct electron tunneling from the donor to the acceptor located at the opposite membrane interfaces, (ii) electron carrier-mediated diffusional

transport across the bilayer and (iii) site-to-site electron hopping down a series of acceptors organized transversely across the membrane.

Transmembrane electron tunneling

Two celebrated early investigations of transmembrane oxidation–reduction were interpreted in terms of direct electron exchange between redox partners bound at the opposite vesicle interfaces. One involved apparent reduction of diheptylviologen [$(C_7)_2V^{2+}$] in the inner aqueous phase of phosphatidylcholine liposomes by EDTA in the bulk phase that was mediated by membrane-bound amphiphilic $Ru(bpy)_3^{2+}$ analogs; the ruthenium complexes acted as photosensitizers and were presumed to function as electron relays by undergoing $Ru(II)$ – $Ru(III)$ electron exchange across the bilayer [105]. The other apparently involved direct electron transfer between photoexcited $Ru(bpy)_3^{2+}$ and MV^{2+} bound at the opposite interfaces of asymmetrically organized anionic DHP vesicles [106]. What was remarkable about these reactions was their apparent rapidity. To compete with photophysical deactivation of $*Ru(bpy)_3^{2+}$, which occurs on the microsecond time-scale, transmembrane oxidative quenching across the DHP bilayer would have to occur with an apparent rate constant of $\sim 10^6 \text{ s}^{-1}$. Likewise, to account for the rate of transmembrane oxidation–reduction in the liposomal system, electron exchange would have to occur across the bilayer with a rate constant very nearly the same as that measured in aqueous solution where close approach of the reactants is possible. However, one expects electron transfer rates to fall off approximately exponentially with distance, as has been demonstrated for redox reactions in various other disordered media [107]. In these cases, the electron-transfer rate (k_{et}) constant can be estimated using the equation

$$k_{et} = k_0 \exp(-2r/a) \quad (16)$$

where k_0 is the rate constant when the reactants are in physical contact, r is the distance of separation and a is a constant whose experimental value typically ranges from 1.0 to 2.0 Å. For the average value of $a = 1.5 \text{ Å}$, one would predict a rate constant $k_{et} \approx 10^{-12} \text{ s}^{-1}$ for a reaction occurring across the full bilayer width of $\sim 40 \text{ Å}$ whose k_0 is 10^{11} s^{-1} ; this represents a characteristic decay time (τ) of over 10^{12} s , 18 orders of magnitude less than the values implied by the experimental data [105].

The dilemma posed by these considerations was resolved for the DHP-organized system when it was noted that upon illumination the initially compartmented MV^{2+} partially leaked out of the vesicles [108]. Thus, the observed reaction actually occurred between reactants adsorbed on the same vesicle surface. The mechanism of this unprecedented light-induced scrambling of MV^{2+} is still not understood. Likewise, subsequent investigations of the PC-organized system provided evidence for transmembrane leakage of a small amount of the compartmented $(C_7)_2V^{2+}$ ion, which then facilitated transmembrane electron transport [109]. Specifically, the reaction characteristics were duplicated when the amphiphilic $Ru(bpy)_3^{2+}$ analog was bound only to the opposite side of the membrane as the oxidative quencher

$[(C_7)_2V^{2+}]$ or when sensitizers that did not bind to the PC membrane at all were present in the external medium. Additional studies using ^{14}C -radiolabeled $(C_7)_2V^{2+}$ demonstrated that transmembrane diffusion of the viologen did occur on relevant time-scales, and a full kinetic analysis of apparent transmembrane reduction of viologens across PC liposomal membranes provided direct evidence for the proposed viologen-mediated transmembrane redox pathway [109]. Thus, in retrospect, it is clear that these reactions did not occur by electron tunneling across the bilayer.

Candidates for bona fide electron tunneling, at least part way across the bilayer, include the reactions of isoalloxazines that have been immobilized by covalent attachment at the β -alkyl position of a phosphatidylcholine surfactant [110], transmembrane reduction of an amphiphilic 4-alkylpyridinepentaammineruthenium(III) ion $[(NH_3)_5Ru-4-(11'-dodeceny)py^{3+}]$ [111] and photosensitized transmembrane oxidation–reduction of aqueous phase donors and acceptors mediated by chlorophyll *a* [112]. In the first of these, the flavophospholipid was shown to be incorporated into PC liposomes without perceptible perturbation of the normal bilayer structure. Reduction of the flavin by externally added $S_2O_4^{2-}$ was biphasic, with the rate of the slower step being independent of the $S_2O_4^{2-}$ concentration, consistent with electron transfer from the reduced flavin substituent in the outer bilayer leaflet to the flavin substituent in the inner leaflet. The flavin moieties were also shown to mediate transmembrane reduction of occluded $Fe(CN)_6^{3-}$ by external $S_2O_4^{2-}$ in a reaction that was weakly coupled to proton transport [113]. The rate constant for the transmembrane redox step was second-order, suggesting a mechanism in which uncorrelated lateral diffusion of the redox partners in the two membrane half-layers led to their transverse juxtaposition, followed by net transmembrane oxidation–reduction. In DPPC liposomes, an abrupt increase in the transmembrane electron transport was observed on going through the gel-to-liquid crystalline phase transition, consistent with this model. However, since the overall process is electrogenic, and requires membrane-depolarizing ion movement to proceed, an alternative interpretation is that ion permeation became rate limiting below the phase transition. The transmembrane redox step was fairly slow, with an apparent $t_{1/2} \approx 10$ s under the experimental conditions. Assuming that the flavophospholipids were incorporated in normal fashion into the bilayer, the flavin groups would be located ~ 7 Å from the membrane interface and, when transversely juxtaposed, separated by ~ 20 Å. Thus, the magnitude of the transmembrane redox step is consistent with an electron tunneling mechanism. Because the ‘flip-flop’ rate of the underivatized phospholipid is extremely slow ($t_{1/2} \geq 24$ h), it was assumed that the reaction could not occur by transverse diffusion of the derivatized phospholipid. It would have been useful to confirm this by direct measurement, however.

One-electron reduction of $(NH_3)_5Ru-4-(11'-dodeceny)py^{3+}$ by externally added reductants followed biphasic kinetics when the complex was bound at both interfaces of PC liposomes, but only the fast step was observed when binding was limited to the external surface [111]. The slow step was first order and independent of the identity and concentrations of added reductants. The rate constant, $k = 10^{-3} s^{-1}$, was unchanged upon adding either the potassium ionophore, valinomycin, or the proton carrier, carbonyl cyanide *m*-chlorophenylhydrazone, to the medium, indicating that, although electrogenic, the transmembrane reduction step was not rate-

limited by charge-compensating ion diffusion. The magnitude of the rate constant is consistent with an effective electron-tunneling distance of ~ 20 Å, which could be achieved if the ruthenium complexes intercalated within the bilayer in a manner envisioned for amphiphilic viologens bearing long alkyl chains (Figure 4). Kinetic 'mapping' studies established that neither the Ru(II) nor Ru(III) ions underwent net transmembrane diffusion on the time-scale of the transmembrane redox step. However, this does not preclude transverse "flip-flop" exchange between Ru(II) and Ru(III) as an alternative mechanism for the apparent transmembrane reduction step.

Based upon a detailed analysis of reaction transients, a mechanism was proposed for chlorophyll a-photosensitized transmembrane oxidation–reduction of aqueous phase donors and acceptors that included electron transfer between juxtaposed Chl a^+ π -cations and Chl a molecules as the transmembrane charge-transfer step [112]. The maximum apparent first-order rate constant for this step was $k \approx 10^4 \text{ s}^{-1}$, which seems large for thermal electron transfer between chlorophyll molecules located at the opposite membrane interfaces, even considering that nuclear activation barriers may be relatively small for this reaction. Transverse 'flip-flop' diffusion of Chl b across the membrane is 10^6 -fold slower than transmembrane redox under these conditions, so this alternative mechanism is almost certainly unimportant. Kinetic mapping studies have shown that some of the Chl a becomes localized within the membrane at sites that are inaccessible to aqueous phase electron acceptors, presumably within the membrane interior [114]. This suggests the possibility of a transverse 'hopping' mechanism involving electron transfer over relatively short distances from buried Chl a to interfacial Chl a^+ , followed by electron transfer from Chl a at the opposite interface to the buried Chl a^+ .

Several studies to probe distance dependences in electron-transfer reactions have been conducted using hydrophobic metalloporphyrins tethered through alkyl chains of varying lengths to hydrophilic groups, the basic idea being that the tether would limit the depth of penetration of the redox center within the bilayer. For example, hydrophilic polyethylenimine was attached to a hydrophobic manganese *meso*-tetratolylporphyrin that was capable of mediating transmembrane reduction of $\text{Fe}(\text{CN})_6^{3-}$ across PC liposomes by the highly hydrophilic dye indigotetrasulfonate (ITSAH₂) [115]. As discussed below, the mechanism of the untethered reaction is thought to be carrier-mediated transport. Electron transport in the tethered molecules was observed only for the longest chain derivatives, for which the minimal heme separation distance was estimated to be about 4 Å. Surprisingly, shorter chain analogs whose separation distance was limited to ~ 10 Å could not catalyze the transmembrane redox reactions. In another study, a series of hydrophobic zinc *meso*-tetraphenylporphine compounds was prepared that contained phosphatidylcholine groups attached via amide linkages to the phenyl rings [116]. Oxidative quenching of MV^{2+} by the triplet-excited zinc porphyrins incorporated into DPPC liposomes occurred only for those complexes for which the maximum distance from the liposomal interface was constrained to ~ 12 Å or less. These studies underscore the limitations of long-range electron transfer within bilayer membranes. However, the actual distances inferred from the data should probably be given only qualitative significance because the tethers are flexible and it has not been shown that the

derivatized complexes can assume their full extended length within the membrane bilayer. In the study with the 'picket fence' zinc porphyrins, for example, the fluorescence properties of the chromophores were consistent with an alcohol-like environment, suggesting an average location near the membrane interface, rather than buried within the membrane hydrocarbon phase [116].

Carrier-mediated electron transport

The mechanism of MV^{2+} -mediated electron transport across DHP vesicle membranes has been identified in systems where $^{\bullet}MV^{+}$ is generated chemically or photochemically in the bulk medium to react with a membrane-impermeable oxidant [$Co(bpy)_3^{3+}$] in the internal aqueous phase [27, 117]. Quantitative kinetic analyses of the decay profiles, including independent determination of the permeability coefficient of the $^{\bullet}MV^{+}$ radical, as well as determination of the extent of viologen uptake under varying reaction conditions, has provided conclusive evidence for two parallel pathways. One pathway involves electrogenic transmembrane diffusion of $^{\bullet}MV^{+}$ and the other involves electroneutral diffusion of the doubly reduced MV^0 species, the latter being formed in small concentrations by disproportionation of $^{\bullet}MV^{+}$, i.e., the reaction $2^{\bullet}MV^{+} = MV^0 + MV^{2+}$. The electrogenic pathway makes a relatively large contribution to the early stages of the reaction, but is sharply attenuated by the developing transmembrane potential; the latter stages are then carried primarily by the electroneutral pathway, which is insensitive to the transmembrane potential. Reaction by both pathways is relatively slow because the intrinsic permeability of $^{\bullet}MV^{+}$ is low and MV^0 , although highly permeable, is present in vanishingly small concentrations owing to the unfavorable disproportionation equilibrium. As a consequence, the flux of MV^0 through the membrane is low. An MV^0 diffusion pathway has also been proposed for viologen-mediated redox reactions across PC liposomes based upon the form of the rate law for transmembrane oxidation–reduction [118]. Analogous transmembrane diffusion mechanisms have been proposed for structurally similar *N*-alkyl-4-cyanopyridinium (C_nCP^{+}) ions, which act as combined oxidative quenchers and redox mediators in photoinitiated transmembrane reactions of aqueous phase-separated donors and acceptors [95]. Because in this case the cyanopyridinium radicals are both the majority carriers and neutral molecules, the transmembrane redox reactions are rapid, occurring on the millisecond time-scale. Surprisingly, the rate constants for diffusion of the $^{\bullet}C_nCP^0$ radicals, measured by transient spectrophotometry, were independent of the *N*-alkyl chain length over the range $n = 1$ –16. As with viologen-mediated electron transport, the oxidized C_nCP^{+} ion was membrane impermeable, and accumulated within the inner aqueous phase following reaction with the electron acceptor located there. By modifying the alkyl chain of the cyanopyridinium ion to include a terminal carboxyl substituent, it has been possible to demonstrate multiple electron transfers by a single mediator [119]. In this case, the reduced cyanopyridinium radical functions to co-transport a proton with the electron in the form of the carboxylic acid substituent. The acidity of the pendant carboxylic acid increases upon oxidation of the cyanopyridinium within the aqueous core of the vesicle, releasing a proton. The now zwitterionic oxidized species can also diffuse as an electroneutral species and

Figure 12. General reaction scheme for photoinduced transmembrane reduction of $\text{Co}(\text{bpy})_3^{3+}$ by dithiothreitol (DTT) across DHP bilayer membranes mediated by 2,4,6-triphenylpyrylium ion (TPP^+). The mediator acts both as an oxidative quencher of $^3\text{ZnTPPS}^{4-}$ and a cyclic electroneutral transmembrane e^-/OH^- antiporter (from [120]).

apparently has sufficient permeability to diffuse back across the membrane and engage in another redox cycle.

A similar strategy to achieve rapid (i.e., electroneutral) cyclic transmembrane diffusion of a redox mediator has been employed that makes use of pyrylium or thiopyrylium ions as combined oxidative quenchers and transmembrane electron carriers. In this case, advantage has been taken of the reversible hydrolytic ring opening to form 1,5-diketones to develop uncharged redox shuttles that function by counter-transport of the electron and OH^- ions [120]. The basic system is outlined in Figure 12. Photoreduction of the pyrylium cation in the external medium to the neutral radical is followed by transmembrane diffusion to the aqueous core, where it reduces an electron acceptor. The oxidized pyrylium ion undergoes hydrolysis according to the dictates of the thermodynamic equilibrium with its diketone form, the diketone diffuses outwardly and the cycle is closed by re-formation of the pyrylium ring. On average, 40 cycles of the redox carrier have been demonstrated without any evidence of degradation of the system; the limiting factor in these studies was the amount of electron acceptor that could be occluded within the vesicles.

Transmembrane reduction of $\text{Fe}(\text{CN})_6^{4-}$ by ITSAH_2 across PC liposomes is mediated by lipophilic iron and manganese porphyrins [121]. The relative rates increased with increasing heme lipophilicity, and were not influenced by adding

lipophilic ions or ionophoric compounds, indicating that the reaction was electro-neutral. This implies a carrier-mediated mechanism, rather than electron transfer between ferri- and ferrohemes in the opposite bilayer leaflets which would necessarily be electrogenic. A mechanism was proposed in which a proton was co-transported with the electron via a water molecule axially bound to the heme. Thus, the ferroheme diffused across the membrane as a neutral molecule bearing an aqua ligand, and the ferriheme diffused as the neutral hydroxo complex. This mechanism was shown to be consistent with changes in medium acidity accompanying the redox reaction; the ability of hemin dimethyl ester to carry SCN^- through a bulk liquid membrane was also demonstrated.

As noted previously, real membranes are characterized by nonuniform free-energy profiles for bilayer permeation. Consequently, molecular dynamics simulations have been used to treat the motion of a solute through a bilayer membrane. These calculations accurately reproduce experimentally estimated values of diffusion [43]. However, because this approach is mathematically complex, it has been applied only to the permeation of relatively small molecules. Approximate methods have been developed based on a simple kinetic scheme for the diffusion of solute molecules M in a four compartment system:

where the subscripts indicate the location of M in the bulk aqueous phase (o), inside the membrane near the outer (mo) and inner (mi) surfaces, and within the inner aqueous volume (i), k_1 , k_{-1} , k_2 and k_{-2} are constants for permeation across the membrane/water interface and k_f and k_r are constants for transmembrane diffusion [122, 123]. The equations which describe the flow of particles from each region are

$$\frac{dn_o}{dt} = k_{-1}[M_{mo}] - k_1[M_o] \quad (17)$$

$$\frac{dn_i}{dt} = k_{-2}[M_{mi}] - k_2[M_i] \quad (18)$$

$$\frac{dn_{mo}}{dt} = k_1[M_o] - k_{-1}[M_{mo}] + k_r[M_{mi}] - k_f[M_{mo}] \quad (19)$$

$$\frac{dn_{mi}}{dt} = k_2[M_i] - k_{-2}[M_{mi}] + k_f[M_{mo}] - k_r[M_{mi}] \quad (20)$$

where n_x and $[M_x]$ are the number and the concentration of molecules M in region x , respectively. The simultaneous solution of Eqs. 17–20 for n_o is an exponential function with the rate constant $\gamma \approx P[(S_o/V_o) + (S_i/V_i)]$ where S_o , S_i , V_o , and V_i are the outer and inner total surface areas and volumes, respectively [123]. Thus, the membrane permeability can be calculated from the transmembrane decay kinetics.

Site-to-site electron hopping

Transmembrane charge separation by sequential electron transfer between adjacent redox centers is epitomized by studies utilizing covalently linked donor–sensitizer–acceptor triad molecules that are vectorially organized across planar bilayer mem-

branes and liposomes [90, 92, 124]. In the studies with liposomes, transient spectrophotometry revealed that photoexcitation of the porphyrin sensitizer moiety is followed by electron transfer to the quinone acceptor and reduction of the porphyrin π -cation by electron donation from the appended carotene donor, the overall result being charge separation across nearly the full bilayer width. When the charge-separated species reacted with lipid-soluble quinones present in the membrane, a chemiosmotic proton gradient developed as a consequence of electrogenic proton translocation associated with the quinone oxidation–reduction cycling. This chemiosmotic potential, which is due solely to the transverse asymmetry of the electron-transport chain, was sufficient in magnitude to drive formation of the phosphoanhydride bond when a properly oriented ATP synthase was also incorporated into the membrane. As such, this system closely mimics biological photophosphorylation processes.

Less sophisticated and well-defined electron transport chains may also develop within bilayer membranes simply by aggregation of redox components. In one study, the protein cytochrome (cyt) c_3 incorporated within PC liposomes was found to mediate electrogenic transmembrane reduction of entrapped $\text{Fe}(\text{CN})_6^{3-}$ by externally added donors with cotransport of protons [125]. Transmembrane electron transfer was suggested to occur through an electron-transport chain formed by dimerization of cyt c_3 because the dominant term in the rate law was second order in cyt c_3 . Aggregation can indeed be expected to lead to an electron-hopping pathway because this remarkable protein contains a cluster of four nonidentical hemes whose center-to-center distances range from 10 to 18 Å. Furthermore, electromagnetic interactions between the iron centers are detectable, and dried films of the protein have anomalously high electrical conductivities [126]. There are several unexplained anomalies associated with these reactions [2a], so the mechanism cannot be taken as established.

An interesting case of metalloporphyrin-mediated photoinitiated transmembrane oxidation–reduction between aqueous donors and acceptors has been reported in which the efficiency of reaction was proportional to the square of the incident light intensity [127]. This dependence implies a two-photon excitation mechanism. Optical spectroscopic and EPR evidence were presented indicating that the lipophilic metalloporphyrins were extensively aggregated within the membrane bilayer. A mechanism involving reaction initiated by oxidative quenching of a doubly excited metalloporphyrin dimer by the aqueous electron acceptor was proposed, although it was acknowledged that an alternative mechanism involving stepwise electron transfer with reaction between a photoexcited triplet porphyrin and a porphyrin π -cation radical as an obligatory second step could not be excluded from the data. Two-step activation schemes involving synchronous photochemical reactions at the opposite interfaces of a bilayer membrane have been suggested for more complex vesicle assemblies containing both lipid-soluble zinc porphyrins and electron acceptors (alloxazines), as well as aqueous donors and acceptors [128]. As envisioned, photoexcitation of a zinc porphyrin near the donor interface results in oxidative quenching by the alloxazine, followed by electron transfer from the donor to the porphyrin π -cation radical. At the other interface, oxidative quenching of a second triplet-excited zinc porphyrin by the aqueous phase acceptor generates another π -cation radical, which is subsequently reduced by an oxidized alloxazine that diffuses

across the bilayer. Cyclic oxidation–reduction of the alloxazine at the opposite interfaces is thought to shuttle a proton, as is required to maintain electroneutrality. Overall, although it cannot be taken as established, the proposed mechanism appears to incorporate elements of long-range electron transfer, carrier mediated proton–electron co-transport and possibly electron hopping.

Strong evidence exists for electron hopping in photoinduced transmembrane redox reactions mediated by C_{60} and C_{70} fullerenes across planar bilayer membranes [129]. Reductive quenching of the triplet-excited fullerene by an aqueous donor (e.g., ascorbate) followed by oxidation of an acceptor (e.g., anthraquinone sulfonate) in the opposite compartments was monitored by measuring the induced photocurrents. The influence of factors such as membrane thickness, dependence upon applied photopotentials and membrane electrostatic charge were inconsistent with a transbilayer diffusional mechanism for the reduced fullerene radical anions [129c]. Furthermore, the charge transient time, measured from photovoltage and photocurrent transients following illumination of a sensitizer adsorbed at the membrane interface in the presence and absence of acceptors, was less than 10^{-6} s [129b]. This is considerably shorter than the time for transmembrane diffusion of large anions (10^{-4} – 10^{-6} s), and provides convincing evidence of charge movement by electron transfer, rather than ion diffusion. Because the diameters of the individual fullerenes are only 7–11 Å, it is assumed that they are aggregated within the membrane to span the bilayer. Rapid electron transport then occurs by electron transfer from particle to particle within the aggregate.

Photoinduced electron transfer across planar bilayer membranes doped with discrete cofacially stacked porphyrin trimers and tetramers has been demonstrated [130]. The proposed mechanism involves a sequence of steps initiated by interfacial oxidation of a photoexcited porphyrin ring adjacent to the aqueous phase containing the electron acceptor, followed by migration of the positive charge by electron hopping to the ring adjacent to the aqueous phase containing the electron donor and electron transfer across that interface [130c].

To summarize, electron transfer across the full width of a bilayer membrane has not been demonstrated and almost certainly does not occur, although direct transfer from one bilayer leaflet to the other may be possible if the redox centers are embedded within the membrane, reducing the effective distance to less than 20 Å. Site-to-site electron hopping also occurs when transversely aligned redox centers or membrane-spanning aggregates of redox molecules form in the bilayer. These processes are electrogenic and must be associated with charge-compensating ion movement to proceed to completion. Transmembrane oxidation–reduction can also occur by transbilayer carrier-mediated diffusion when lipophilic redox-active molecules and ions are present in the membrane; these reactions can be either electrogenic or electroneutral.

Volume IV

Part 3

Gas-phase Systems

1 Introduction and Theoretical Background

Yehuda Haas

Electron transfer is usually carried out in bulk, condensed matter. In the gas phase, the lower concentrations of the donor and acceptor reduce the chance of an encounter between them in comparison with condensed phases. Furthermore, in the absence of a solvent, no stabilization of the separated ions by solvation is possible, enhancing the chance of charge recombination. The volume of published papers in this field is therefore much smaller for gaseous systems than for condensed matter. Nonetheless, gas-phase systems are in principle simpler to analyze and comparison with theory is more straightforward. The analysis of electron transfer in condensed systems usually starts from the (sometimes experimentally inaccessible) gaseous system. Therefore, efforts to study electron transfer in the gas phase continue, and have indeed shed much light on the mechanism of the process.

This Part deals with gas-phase systems in general, but the emphasis is on systems studied in supersonic jets. Chapter 2 by Soep and Mestdagh in this Part introduces the subject. Gas-phase electron-transfer reactions have been studied since the 1930s in the bulk, and later in crossed molecular beams. When the electron donor is easily ionized, as is the case with the alkali and alkaline earth metals, large reaction cross-sections are measured with acceptors having a large electron affinity. The very large cross-sections were explained by the harpoon mechanism, still the starting point for the analysis of these reactions. Ground-state reactions are usually characterized by a barrier, requiring energy input into the reactants. Efforts to understand better the stereochemical requirements of these reactions led to increased interest in well-defined binary structures containing the donor and the acceptor. Supersonic jet cooling is a relatively simple method for preparing weakly bound van der Waals complexes in the gas phase.

The jet-cooling method is now so widely spread that it does not need a separate introduction. In principle, all that is needed is mixture of the system under study in a suitable carrier gas (e.g., helium) which is expanded from a moderately high pressure (1–5 atm) to high vacuum through a small orifice. This rapid expansion creates a jet that emerges from the orifice and very efficiently cools the system to

temperatures as low as 1–10 K. Adding a ‘solvent’ molecule to the mixture provides a means to prepare solvated clusters of different sizes. The study of photoinduced electron transfer in gas-phase systems has been almost completely dominated in the last 10 years or so by this method. The reasons for this are obvious:

- For electron transfer to happen, two molecules are required—a donor and an acceptor. The easy formation of van der Waals adducts in the cold environment of the supersonic jet allows the future donor and acceptor to be in close contact before absorbing the light. This makes it possible to work under collision-free conditions.
- The low temperature prevailing removes spectral congestion due to hot rotational and vibrational bands. Therefore, subtle effects can easily be measured. In particular, different structural isomers can be studied.
- It is possible, in principle and in practice, to synthesize clusters of different sizes and shapes. In particular, it is possible to prepare an adduct and ‘solvate’ it with a gradually increasing number of solvent molecules. This allows, in principle, the study of the effects of solvents on the electron-transfer process.
- In recent years, several new techniques have become available for the more detailed study of jet-cooled systems. These techniques, to be described briefly below, and at greater length in the following chapters, open up new ways for characterizing the species formed in the jet expansion.
- The collision-free situation is in principle easier to compare with theory, since complications due to interactions with the solvent or other surrounding entities are removed.

Supersonic jets have limitations. The very low number density of the adducts requires special methods for analysis. These are usually state specific, and can be easily applied to the reactants, which are produced in a small number of quantum states. The products are usually formed in many quantum states, making them difficult to observe in real time. The method allows the preparation of a limited number of binary clusters—those structures that form stable adducts in the ground state. In the bulk, thermal energy allows the formation (perhaps only for a short time) of many other conformations. It is not clear at this point whether the structures studied in supersonic jets are the ones important in the bulk. The low temperature prevailing in the jet usually precludes observation of ground-state reactions. It is necessary to initiate the reaction by some means of excitation, usually realized by the absorption of a photon. Excitation is subject to Franck–Condon restrictions, and the subsequent dynamics of the cluster may be dominated by the vibrational modes controlling the departure from the Franck–Condon region. In particular, long-range interactions (i.e., for distances exceeding the van der Waals equilibrium distance) cannot be studied.

In this Part, the emphasis is on experimental advances, mainly over the last dozen years. This introductory chapter outlines some unifying aspects of the work to be presented in the following chapters, and also reviews briefly the theoretical background.

1.1 Some Novel Experimental Advances

The main advantages of jet-cooled systems are as follows:

- Direct probing of isolated molecules.
- The stepwise study allows, in principle, the role of the solvent in the photo-physical process under investigation to be established, in the present case the promotion of electron transfer by the solvent.
- These systems are better suited to detailed comparison with theory than any other experimental arrangement.

Early studies, using a simple one-photon excitation of fluorescence, or resonance-enhanced multi-photon ionization (REMPI), established the fact that electrons can be transferred in gas-phase systems (Chapters 2 to 5 of this Part). Mass selection sometimes allowed the discrimination between different-sized clusters of the type AD_n or AD_nX_m , where A and D are the acceptor and donor molecules, respectively, X a solvent molecule and n and m integers. However, it soon became evident that in the jet, several isomers having the same molecular formula are synthesized simultaneously. Their photophysical properties were different, making the elucidation of structure–reactivity relationships a major research goal. Some new techniques have been developed to address this issue. They are usually based on the use of several laser sources, taking advantage of the high power and high resolution available. Examples are as follows.

In hole-burning spectroscopy, used in conjunction with either fluorescence or ionization detection, two pulsed lasers are used, usually both in the nanosecond regime. One (the ‘burn’ laser) is operated at high power, and is scanned across the absorption spectrum. It excites one of the isomers, depleting the population of this particular species. A second, low-power laser (the ‘probe’ laser), fired after a suitable time delay, is tuned to one of the excitation spectrum vibronic bands of the system, and the fluorescence (or ionization) induced by it (the ‘signal’) is monitored. Whenever the frequency of the burn laser corresponds to excitation of the isomer that absorbs the probe laser, the signal is reduced. This reduction appears as a ‘hole’ that is burned in the signal intensity due to the probe laser. If a different isomer is excited (or a different vibrational level of the same isomer), no change in signal intensity is incurred. The method has been widely used to establish the number of different isomers (Chapter 4, of this part). A recent variant used infrared laser as the probe (Chapter 3 of this Part), although application to electron transfer has not yet been reported.

Charge transfer to solvent (CTTS) has long been studied in liquid solutions of negative ions. The method is now widely investigated in supersonic jets (Chapter 5 of this Part). Size selection of these charged species is easily accomplished using magnetic and electric fields. The mass-selected ions are then subjected to monochromatic laser excitation, causing photodetachment of the electron. The kinetic energy of the electron is monitored as a function of cluster size, allowing the prob-

ing of electron transfer between the anion and solvent molecules. A connection with bulk properties is easily established in this way. Pump–probe techniques are employed in the time-resolved study of the photodynamics of monoanions. A femto-second laser pulse (the pump) electronically excites the anion, and a second femto-second pulse (the probe) induces the photodetachment of the electron. The kinetic energy of the released electron is found to depend strongly on the cluster size.

Examples of such systems include alkali metal atoms solvated by ammonia and by water; four solvent molecules appear to fill the first solvation layer. Thus, in $\text{Li}(\text{H}_2\text{O})_n$, when $n > 4$, the valence electron appears to move out into the second solvation layer, forming $\text{Li}^+(\text{H}_2\text{O})_n^-$. Another example is solvated iodine anions [such as $\text{I}^-(\text{CH}_3\text{CN})_n$]; photoexcitation leads to the transfer of an electron to the solvent even for $n = 2$. The nature of the excited state is determined by the entire arrangement of the solvent molecules, as expected for a CTTS state.

Still another technique uses one laser to prepare the initial state and a different laser to photodissociate the electron donor. The second laser competes with the rate of electron transfer (Chapter 4 of this Part). This method has been used so far only in the nanosecond regime, and could not probe fast electron-transfer rates. Its extension to picosecond or even femtosecond time-scales should be most fruitful.

As detailed in Chapter 3 of this Part, TICT molecules are an example of the extreme importance of solvation in promoting electron transfer. Almost all molecules studied in isolation do not exhibit the characteristic CT fluorescence. When solvated in the jet, some show pronounced CT emission. The role of solvation has been shown to be crucial also in excited-state proton transfer reactions—there is a minimum size at which a proton is transferred in clusters of potential proton donors solvated by ammonia (or water). A similar trend appears to be found in the TICT systems. A major factor is the change in the energy level diagram—the charge-transfer state is affected by solvation in a different manner than the locally excited state. Thus, the crossing point between the states is changed apparently in a way that promotes electron transfer. The application of modern experimental methods to the detailed study of these systems is expected to unravel the factors controlling their dynamics.

These examples are only a few demonstrations of the general effort to use cluster reactions as a bridge between isolated binary systems and bulk reactions. The cluster isolated chemical reaction (CICR) technique elaborated in Chapter 2 of this Part is an important advance in that direction.

1.2 Theoretical Background

The theory of photoinduced electron transfer is based on the classical work of Marcus, Hush, Mulliken, Murrell and many others and it has been extensively reviewed in Chapter 1 of Part 1. The study of isolated, ultra-cold systems provides an opportunity to check some of the basic assumptions of these theories. In particular, one can easily discriminate between different structural isomers of a given system

and probe separately locally excited (LE) and charge-transfer (CT) states. As explained in Chapters 2 to 4 of this Part, it is often possible to monitor the evolution of an LE state to a state. In that sense, the jet studies support the three-state model for weakly coupled systems: the acceptor and donor are viewed as separate species, weakly interacting. The Hamiltonian operator of the complete system may be written as the sum of the Hamiltonians of the two systems, with only weak interaction. This leads to the widespread use of the Fermi golden rule, as is often done in radiationless transition theory. In this picture, initial photoexcitation is into the LE state, which is coupled to the lower lying CT state by a coupling term V . Irreversibility is ensured by the higher density of vibrational states of the CT state.

In some cases, however, electron transfer is very rapid. This has been demonstrated for systems consisting of two separate molecules (e.g., anthracene and dimethylaniline), for solvated TICT molecules (not for the isolated ones) and for some rigid bridged systems. In these cases, it may be inappropriate to use the weak coupling scheme and one has to consider some curve-crossing mechanism. The classical Marcus curve-crossing model assumes motion along a single coordinate. Recent studies of TICT molecules indicate that at least two coordinates are involved. This situation is typical of cases where conical intersections are involved. These unique loci on the molecular potential surfaces are believed to lead to very efficient curve crossing. Their connection with photoinduced electron transfer has not yet been elucidated.

2 Electron-transfer Reactions Involving Atoms, Molecules and Clusters

Benoit Soep and Jean Michel Mestdagh

2.1 Introduction

This chapter reviews several gas-phase studies involving atoms, simple molecules, van der Waals complexes and clusters. Electron-transfer reactions are central processes in a variety of scientific disciplines as outlined in a recent review by Bixon and Jortner [1]. We highlight here the current understanding in the dynamics of the gas-phase electron-transfer reactions, and end the chapter by presenting work which intends to bridge the gap between the standard knowledge of electron-transfer reactions in the gas phase and in condensed phases.

Electron-transfer reactions between a donor D and an acceptor A have been widely studied in liquid solutions. Marcus first proposed the following multistep mechanism to account for these reactions [2, 3]:

The first step forms the activation complex $(\text{AD})^\ddagger$ along a reaction coordinate which is a combination of the nuclear coordinates of the reactant pair with those of the solvent. The activation complex is actually doubly degenerate. Besides the form $(\text{AD})^\ddagger$ where no electron has transferred, which is hence close to the reactant electronic configuration, a second form exists where an electron has jumped from the donor to the acceptor for forming the ion pair A^-D^+ . The second step of the reaction corresponds to the electron jump. The resulting ion pair then evolves to the reaction products. Gibbs energy G is the essential quantity to follow along the reaction coordinate [in the gas phase, however, as we shall deal mostly with direct reactions

Figure 1. Gibbs energy diagram of a typical electron transfer reaction $A + D \rightarrow A^-D^+$ in solution. Adapted from Ref. [3].

under isolated conditions, the relevant quantity is the energy E (see below)]. Its variation is shown in Figure 1. As shown, this early mechanism was assumed to follow a single coordinate, and the electron jump at the transition state was assumed to be Franck–Condon limited [no atomic movement during the $(AD)^{\ddagger} \rightarrow A^-D^+$ transfer]. This mechanism is described in many review papers, e.g., [4–7]. The modern approach to excited-state electron transfer in solution has abandoned the picture of a movement along a single reaction coordinate. It has adopted a quantum mechanical picture where electron transfer appears as a radiationless process between two states. The *doorway states* describing the reactant pair AD in its environment are then coupled to a dissipative manifold describing the solvated ion pair A^-D^+ [1]. In excited-state electron-transfer processes, this can also be termed the excitation of a locally excited state decaying into the charge-transfer quasi-continuum.

Electron-transfer reactions are also gas-phase processes, which truly correspond to the aims and model examples for reaction dynamics. They have been studied for more than 60 years, and appear as invaluable benchmarks to unravel the interplay between forces during chemical reactions. As a first approximation, electron transfer can be considered as localized and proceeds instantaneously when the reactants move towards each other along the reaction path. The electron transfer leads to a sudden release of forces which drive the further dynamics of the reaction. Hence visualizing and modeling the effect of these forces should be a fairly easy task.

An important class of the gas-phase electron-transfer reactions is well described, at least qualitatively, by the model named pictorially the ‘harpoon model’, which was proposed originally by Michael Polanyi [8] to account for exceptionally large cross-sections in the oxidation reaction of alkali metal atoms by halogen molecules. It is striking to observe that such a simple model is still a useful tool to rationalize these reactions. It is illustrated in Figure 2.

Figure 2, which describes harpoon reactions in the gas phase, has strong relationships with Figure 1, which pictures the Marcus mechanism of an electron-

Figure 2. Schematic energy diagram of the harpoon model for describing the $\text{Na} + \text{Cl}_2 \rightarrow \text{NaCl} + \text{Cl}$ reaction.

transfer reaction in solution. In both cases, the transition state of the reaction corresponds to the crossing between an ion-pair curve with a covalent curve. The essential difference is in the way this crossing is accessed. This difference shows up in the definition of the reaction coordinate, which is obviously much simpler in the gas-phase process. This simplification also has its counterpart in the fact that energy considerations prevail in gas-phase processes whereas free energy terms, including level densities and a transition state, must be considered in solution. Moreover, it must also be borne in mind that the condensed phase not only affects the coordinates defining the ion-pair intermediate but also helps to stabilize it.

The gas phase has many advantages when studying primary reaction mechanisms, since all the physical parameters which characterize the reaction product or the reaction intermediate are, in principle, accessible to the experiment: mass, energy, internal energy distribution (E, V, R), product velocity mapping and charge distribution. Also, interestingly, the use of clusters of increasing size allows one to approach the conditions of 'real' reactions in the condensed phase. In this context, electron-transfer reactions between neutral reactants are convenient probes to follow the forces in the course of chemical reactions.

Of course, the very simple harpoon model at the beginning has been considerably refined and more sophisticated approaches are currently used also. This chapter aims to review such reactions. This has obliged us to omit interesting reactions which are not directly relevant to the harpoon model, such as the electron-transfer reactions of buckminsterfullerene, C_{60} [9], and charge-transfer reactions, which have also produced a considerable literature [10]. Reactions of metal ions are also not treated here. They appear elsewhere in this Part (see Chapter IV.3.5). Moreover, although not centered exclusively on electron-transfer reactions, extensive reviews are available on the ion chemistry of transition metals, either bare [11] or ligated [12].

2.2 Experimental Methods

Gas-phase electron-transfer reactions have been studied using all the experimental methods which are of common use in the reaction dynamics community. These methods have been extensively described in the literature, and it is not necessary to describe them again in detail. We just need to recall a few points, which are necessary to understand the origin of the results discussed in the remainder of the chapter, and only the most recent and comprehensive reviews and a few original papers describing the principal techniques are referred to hereafter. It must be mentioned that the techniques used to study reactive collisions are in very wide use and have also been used to investigate non-reactive collisions, both inelastic and elastic.

Except for a very few studies, experimental investigations in the field of reaction dynamics use one or two molecular beams to prepare the reactants. An impressive compilation of information concerning both the molecular beam technique and its use in reaction dynamics can be found in a book edited by Scoles [13]. The book also includes a thorough description of the tools used to characterize the reaction products.

Crossed molecular beam machines count among the experimental arrangements which allowed a significant breakthrough in reaction dynamics. A recent review by Casavecchia et al. shows how improvements in the crossed molecular beam technique made possible recent progresses in the understanding of gas-phase reaction dynamics [14].

The first aims of crossed molecular beam techniques were to ensure the single collision regime and to define well the kinematics of the collision by fixing the collision energy and the direction of the relative velocity of the colliding partners. The first property was necessary to isolate a single reactive event and to study its dynamics, free of external perturbations. The last two properties allowed one to investigate reaction cross-sections as a function of the collision energy, and also, very important, to determine how cross-sections vary when changing the spatial orientation of one or both reactants with respect to the relative velocity vector of the collision. This led to the determination of scalar quantities in the first case (cross-sections describe the transfer of population into final states) and of vector quantities in the second case, i.e., quantities describing the transfer of orientation, of alignment or of higher tensorial orders from a non-spherical state into another. The systematic search of vector quantities in reaction dynamics led to a new field, *reaction stereodynamics* [15]. Its progress is covered by several special issues of the *Journal of Physical Chemistry*, the latest one appearing in 1997 [16]. Reaction stereodynamics now reveals its true nature, an elegant way of controlling atomic and molecular collisions [17].

An important issue in reaction stereodynamics must be considered. Experiment and vector preparations are usually performed in the laboratory reference frame (space fixed) whereas the important preparation for the reaction is the molecular reference frame (body fixed) which rotates during the collisions at a non-constant angular velocity. This leads to numerous difficulties, which have motivated an important literature reviewed in Ref. [18]. As far as stereodynamics considerations are

concerned, the multi-coincidence detection of all the products of the same reaction must be highlighted as a very promising direction. The description of the technique and important achievements are given in Refs. [19–23].

When the crossed molecular beam geometry is associated with a movable detector, rotatable about the crossing zone of the molecular beams, it is possible to measure both the angular and translational energy distribution of the reaction products. The important breakthrough came with the use of a universal detector which allowed one to go beyond the simple alkali metal atom chemistry [24, 25]. The full dynamic picture of many types of reactions then became available. The latest generation of crossed molecular beam equipment was constructed recently. It improves the sensitivity of the detection in several ways: (i) by arranging the detector in ultra-high-vacuum oil-free chambers [26, 27]; (ii) by using tunable synchrotron radiation rather than electron impact to ionize the reaction product to be detected [28, 29] (several applications illustrating the possibilities opened by this technique appear in Refs. [30–32]); (iii) by using the *velocity map imaging* technique, which gives easy access to the velocity–flux contour map, which summarizes the dynamics of the reaction [33–36].

The crossed-beam geometry can also be used to map the angular distribution of chemiluminescent reaction products. The videochemiluminescence technique has been introduced for this purpose. It was exemplified on the $\text{Ba}({}^1\text{P}_1) + \text{N}_2\text{O} \rightarrow \text{BaO}({}^1\Pi) + \text{N}_2$ reaction where the angular distributions of the long-lived $\text{BaO}^*({}^1\Pi)$ product were imaged using a CCD camera [37, 38].

A variant of the crossed-beam geometry, simpler but efficient in some cases, is the beam-gas arrangement. It leads usually to much larger signal than in the crossed-beam configurations, at the expense of a less accurate definition of the reaction kinematics. It is used fairly often to study the total cross-sections of chemiluminescent processes, especially when the species which is to be put into the beam is refractory, as are the transition metals [39, 40]. Reactions of alkaline earth metal atoms have been studied by this technique [41].

The use of optical techniques, either associated with crossed-beam or beam-gas arrangements, was an important landmark in reaction dynamics since it allowed both the preparation of the reactants and the analysis of the reaction products by laser-induced fluorescence. The reactant preparation consists in depositing energy into a specific state, in order to investigate its reactivity, and also to change its spatial orientation and alignment when the system is not spherically symmetric. The introduction of this technique into reaction dynamics was pioneered by Zare's group. A lot of insight can be found in Ref. [42].

An optical technique involving Doppler spectroscopy can also serve to gain insight into the angular and velocity distributions of reaction products, as reviewed in Ref. [43]. Finally, the Doppler method has been associated with the imaging technique. This is the so-called *Doppler-selected time-of-flight* technique, which is the most powerful one to obtain information on the three-dimensional (3D) velocity and angular distribution of the reaction products [44–46].

The experiments performed under the crossed-beam or the beam-gas arrangement document full collisions, where the system evolves on a single or on several

potential surfaces, from an infinite separation of the reactant to the infinite separation of the reaction products through the transition state of the reaction. The technique of van der Waals clusters is an elegant way to bypass the entrance channel of the reaction, by blocking the reactants close together in a fairly well-defined geometry. The reaction is initiated by laser excitation, near the transition state. Varying the wavelength of the laser allows the reaction to be initiated at various configurations about the transition state. It therefore allows one to study spectroscopically the access to the transition-state region of the reactions. This gives, of course, a very different and complementary insight into the reaction to full collisions [47–50].

More recently, the use of picosecond and femtosecond lasers in reaction dynamics opened up the field of femtochemistry, which was pioneered by Zewail [51–54]. The idea of these reactions is to photoinitiate the reactive process in a van der Waals complex. Sometimes, the process that is initiated is a simple dissociation or the isomerization of a free molecule. In each case, the reaction is initiated by a first ultrashort laser pulse (the pump pulse). It is analyzed after a certain delay by a second pulse (the probe pulse). This gives access to the reaction dynamics on the pertinent time-scale where chemical bonds are broken and others are formed. Depending on the system, this typically lasts between a few tenths of femtoseconds to hundredths of picoseconds. Recently the techniques of stereodynamics have been combined by Zewail and co-workers with femtosecond analysis [55, 56] to label specific reaction channels in electron-transfer reactions.

2.3 The Harpoon Model and Beyond: a Historical Review

2.3.1 The Early Age: the Harpoon, a Model to Describe Reactions of Ground-state Alkali Metal Atoms

The reactions of ground-state alkali metal atoms with halogen molecules have been studied extensively over many decades. The flame experiments by Michael Polanyi's group revealed their exceptionally large cross-sections in the early 1930s [8]. These reactions have attracted detailed crossed molecular beam studies for over 30 years [57–59]. The well-accepted picture to interpret these reactions is the harpoon mechanism, which was proposed originally by Polanyi [8] and was put in a semi-quantitative form by Magee [60]. Gislason has reviewed the early efforts to make it quantitative [61].

According to the harpoon model, the reaction of a ground-state alkali metal atom M with a halogen molecule X_2 proceeds through a long-range electron transfer from the HOMO (highest occupied molecular orbital) of the alkali metal atom (the electron donor) to the LUMO (lowest unoccupied molecular orbital) of the halogen molecule (the electron acceptor), thus forming an $M^+-X_2^-$ complex, which decays to $M^+X^- + X$. In this mechanism one electron has left the HOMO of the alkali metal atom M and has entered into the LUMO orbital of the halogen mole-

cule X_2 . It is the origin of the force which pulls the molecule apart and, as we shall see below, determines both the angular distribution of the reaction product and its internal energy.

The harpoon model has been used on a large variety of systems, far beyond the alkali metal–halogen systems for which it was proposed originally. It is therefore necessary to describe the model on a more general basis by considering the reaction

where D is the electron donor (often a metal atom or an electronically excited metal atom of low ionization potential) and AB a molecule, which acts as an electron acceptor to form temporarily AB^- , which then comes apart as $A^- + B$.

Two crucial parameters determine the dynamics of the reaction. The first is the $D \cdots AB$ distance at which the electron transfer occurs, i.e., the distance R_c for which the ion-pair potential $D^+ \cdots AB^-$ crosses the covalent curve $D \cdots AB$. Assuming a flat covalent curve and R_c large enough for the Coulomb interaction to be dominant, the crossing occurs at

$$R_c = \frac{14.4}{IE - EA} \quad (3)$$

where R_c is in Å and the energies IE and EA in eV, IE being the ionization energy of the electron donor D and EA the electron affinity of the acceptor AB . This expression, sometimes called Magee's equation, could be refined [61], but it is often sufficient to anticipate the important aspects of the reaction.

At this point, when following the terminology of Truhlar and Dixon [62], the harpoon mechanism appears as an *entrance-channel model in a single-surface reaction*. This terminology highlights the fact that the access to the transition state of the reaction involves a movement along a single coordinate in the entrance channel of the reaction, on a single potential energy surface (PES). It is obvious that, even when staying with simple models, efforts have to be made to include the necessary multi-coordinate character of the reaction. This is the role of the second dynamic parameter, which is discussed in the next paragraph.

The second important dynamic parameter mentioned above is the shape of the AB^- potential, which promotes the AB^- dissociation [57, 63]. As we shall see, this parameter is the key to account for the shape of the differential cross-sections measured experimentally. Figure 3 shows the angular distribution of the monohalide product in a family of reactions. All these reactions are called *reaction* according to reaction dynamics terminology. The reaction is dominated by the *impulsive regime* and the product angular distribution has a strong forward–backward asymmetry. In the extreme situations of the $K + CH_3I$ and $K + Br_2$ reactions, the product is respectively backward (scattering angle 180° from the incoming direction of potassium) or strongly forward peaked. This regime occurs when the collision complex breaks up before it can rotate through a half turn. In contrast, an *indirect reaction* involves a long-lived (or persistent) complex, and the product angular distribution has a forward–backward symmetry [64]. One such example is shown later in Figure

Figure 3. Center-of-mass angular distributions of an alkali metal monohalide compound in five gas-phase electron-transfer reactions as labeled. Forward scattering is to be found around 0° and backward scattering at 180° . Adapted from Ref. [63].

5. Grice has derived a microcanonical theory of reactions decaying from a persistent complex [65].

Let us discuss the two extreme situations of direct reactions observed in Figure 3. Then we shall examine an example of an indirect reaction.

When the electron is transferred to an antibonding orbital, the AB^- potential is strongly repulsive along the $A^- \cdots B$ coordinate, thus kicking the $D^+ A^-$ product away from B . Sideways or backward scattering is expected in this case. A representative example is the reaction [66]

which is probably one of the most often studied in the whole field of reaction dynamics. It exhibits further constraints: the distance R_c is short and the acceptance angle $K-I-C$ for an efficient electron transfer is small [67–69]. This makes the reaction of the rebound reaction type, with most products scattered in the backward hemisphere. It must be mentioned, however, that despite many efforts, the dynamics

of this reaction are still not fully understood. A recent paper extensively reviews the current knowledge about this reaction and identifies the problems still open [69].

In contrast, forming AB^- near its dissociation limit requires the Coulomb field of the positive ion to stimulate dissociation of the molecular anion. This situation is encountered when the molecule has a large electron affinity. In this case, the crossing distance R_c is large and the dynamics of the reaction are well described by the spectator stripping model, where the reaction product is strongly forward peaked [70]. This pictorial formulation leaves unaffected the neutral moiety of the molecular reaction partner, which plays the part of a spectator in the reaction. A representative example is the reaction [71]

After these two examples, it should not be thought that reactions described by the harpoon model are necessarily direct. This was the case with reactions 4 and 5 because they are very exoergic and the molecular negative ion is unstable. In contrast, in the almost thermoneutral reaction of Cs with NO_2 , NO_2^- is a stable ion, and the charge-transfer complex $Cs^+ \cdots NO_2^-$ corresponds to a deep well along the reaction coordinate. Hence the reaction proceeds from a persistent complex, with a forward-backward symmetry in the angular distribution of the reaction product CsO [72].

These three examples illustrate the goal of the reaction dynamics community during the late 1960s and 1970s: to build a catalog of some major features of potential-energy surfaces and to indicate, in a qualitative fashion, the consequences of these features for the reaction dynamics. Developing this concept led to an impressive series of papers, which are summarized in comprehensive review papers by J. C. Polanyi [70, 73, 74a]. These dynamic approaches were constructed on very general potential energy surfaces, with no reference to a particular process. The same methodology is currently revisited in order to help understanding the global shape of the product energy distribution in indirect three-atom-reactions going through the temporary formation of a collision complex [74b]. Of course, these very general approaches can therefore be applied to any class of gas-phase reaction, including the present electron-transfer reactions. However, the electron-transfer reactions, which are relevant to the harpoon mechanism are relatively simple as the electron transfer is sudden, and the shape of the potential surface on which the reaction proceeds is fairly simple to guess qualitatively.

The mechanism of the electron transfer and the subsequent dynamics of the system have both been oversimplified at the moment. A more refined model of the dynamics is discussed in the next section: the direct interaction with product repulsion (DIPR) model and its variant called DIPR-DIP (DIP-distributed as in photodissociation). The purpose of sections 2.4 and 2.5 is to explicit the multi-dimensional and multi-PES character of the electron jump step.

2.3.2 A First Multi-dimensional Reaction Model: the DIPR-DIP Model

Readers may wonder why we focus our attention on simple models when modern high-speed computers can handle full quantal calculations. A very recent example of this is furnished by the work of Truhlar and co-workers on the $Na \cdots HF$ system

[75]. However, simple reaction models are very useful in giving a clear, although often semi-quantitative, understanding of reaction mechanisms. Several simple classical models of this type have been proposed to account for direct reactions [62, 76].

We focus our attention on the DIPR (direct interaction with product repulsion) model and its variant, the DIPR-DIP model, mainly because it can be used to predict an entire range of dynamic observables in chemical reactions: angular and recoil velocity distributions, rotational energy and orientation and vibrational energy of the reaction products. It is also able to account for the switch from the rebound to the stripping reaction mechanism for a given system when the collision energy is increased. The beauty of the model is its ability to include semiempirical parameters, each of which is related to a different physical phenomenon.

The DIPR model presumes that the reaction is initiated by a sudden change of coordinate, as suggested by the harpoon model, when the valence electron of the donor D is transferred to the electron acceptor AB. The basic dynamic idea of the model is that the angular and energy distributions of the product AD are mainly determined by a monotonic energy release along the A^--B coordinate after the electron jump. This model was proposed originally by Kuntz and co-workers to account for the direct reactions of an alkali metal atom with a halogen or a halide molecule to give an alkali metal halide product [77–80].

More precisely, the DIPR model is founded on the following set of assumptions, as shown in the pictorial representation in Figure 4.

- AB is initially in the ground rotational and vibrational level.
- The $D + AB$ system evolves on an essentially flat potential surface. This initial movement has a negligible effect on the dynamic behavior of the reactive trajectories.
- The electron jump forming the complex $D^+ \cdots AB^-$ takes place at a distance R_c between reactants. A parameter linked to stereodynamics can easily be introduced at this point into the model: the electron jump probability as a function of the $D-A-B$ angle at the electron jump distance.

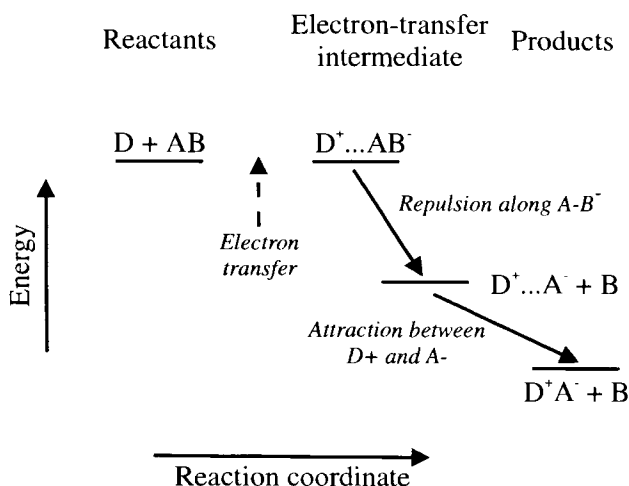

Figure 4. Schematic description of the energy release according to the DIPR-DIP reaction mechanism.

- A change of coordinate follows the electron jump, which turns on the sudden repulsion between A^- and B. Considering that the electron distance R_e is large, no interaction is assumed between D^+ and the departing B moiety.
- An attractive interaction between D^+ and A^- follows the $A^- \cdots B$ repulsion. The attractive and repulsive energy releases are presumed to be separable, and the attraction is assumed to be slower than the repulsion.

If the energy release along the A–B coordinate is a substantial fraction of the total exoergicity (more than 10 %), then the model was found to do very well in reproducing product state distributions [77].

Herschbach [58] noted a striking similarity between the recoil energy distribution of Cl atoms in the $H + Cl_2$ reaction and that observed in the photodissociation of Cl_2 . This suggests that the electron attachment to the molecule is essentially a vertical process, hence he proposed the DIP extension to the model, which makes the AB repulsion after the electron jump analogous to that encountered in photodissociation experiments. This provided the necessary empirical basis for estimating the parameter of the repulsive interaction. All the mathematical expressions relevant to the model were given by Truhlar and Dixon [62]. Zare and co-workers extended the model to chemiluminescent reactions and a full account of the new model is given in Ref. [81]. It was used to predict successfully the product state distribution in the reaction $Ca(^1S_0) + F_2 \rightarrow CaF(B^2\Sigma^+) + F$.

The DIPR model is often used to help in understanding the stereodynamics of direct reactions [82–85]. The important parameter of the model is thus the electron-transfer probability as a function of the molecular orientation. The same parameter, which actually defines the best geometry of the system in the electron transfer step, also plays a role in determining the product alignment in chemiluminescent reactions [86, 87]. A new model has been introduced recently, the anisotropic impulsive model [88]. It is conceptually close to the DIPR model, and also helps to determine the preferred angle of approach between the reactants.

2.3.3 The Double Harpoon: a Mechanism Adapted to Alkaline Earth Metal Atom Reactions

Alkaline earth metal atoms have fairly low ionization potentials, as have alkali metal atoms (e.g., 5.21 and 5.14 eV for barium and sodium, respectively [89]). Hence the reactions of alkaline earth metal atoms with oxidizing molecules are also expected to be initiated by an electron transfer and should follow the harpoon mechanism. However, alkali metal atoms are monovalent species, whereas alkaline earth metal atoms have two valence electrons. Hence peculiarities are to be expected in the alkaline earth metal reaction dynamics, especially when doubly charged products such as BaO are to be formed [90]. The second valence electron also opens up the possibility of chemiluminescent reactions, which are largely absent in alkali metal atom reactions [91, 92]. The second electron causes the existence of low-lying excited states in the product.

Reactions of ground-state alkaline earth metal atoms have been the subject of too

numerous studies to be reviewed here thoroughly. A comprehensive compilation of work prior to 1988 was made by Menzinger [92]. Many references can also be found in earlier review papers and book chapters [91, 93, 94]. We restrict ourselves here to studies, which highlight a concept not yet introduced in the present chapter, the double harpoon, which involves both singly and doubly charged ion-pair intermediates in the reaction. This concept was introduced originally by Menzinger to account for chemiluminescence in reactions with halogen molecules [91]. It was refined further by Lee and co-workers to account for crossed molecular beam studies of the formation of ground-state products [90]. We shall use the model again when considering reactions of electronically excited alkaline earth metal atoms.

Since alkaline earth metal atoms have two valence electrons, it is convenient to distinguish between reaction products, which have a single ionic bond such as BaCl (Ba^+Cl^-) from products having a double ionic bond in the ground state such as BaO (BaO has the structure $\text{Ba}^{2+}\text{O}^{2-}$ in the ground state and Ba^+O^- in the lowest excited states).

Reaction products with a single ionic bond

The reactions of alkaline earth metal atoms with halogen molecules, either forming alkaline earth metal monohalides or leading to chemi-ionization, represent an important case study in the reaction dynamics of divalent systems [91, 92, 95–100]. Let us take as an example the reaction

The reaction product BaCl has the structure Ba^+Cl^- where a single electron is transferred from barium to chlorine. This reaction channel thus correlates adiabatically to the single electron-transfer intermediate Ba^+Cl_2^- . Chemi-ionization is also observed as a minor channel in the $\text{Ba} + \text{Cl}_2$ collision:

The structure of the product BaCl^+ is close to $\text{Ba}^{2+}\text{Cl}^-$. The product channel of reaction 7 thus correlates to the double electron-transfer intermediate, whose structure is probably $\text{Cl}^-\text{Ba}^{2+}\text{Cl}^-$ [91, 92].

Herm and co-workers have measured the BaCl angular and recoil velocity distribution from reaction 6 [101]. As expected, this reaction channel tells little about the role of the second valence electron of barium. The product is forward peaked as in alkali metal–halogen reactions, and is close to the spectator stripping limit. This contrast with reaction 7, where the product BaCl^+ is backscattered [96, 97]. This suggests a very restricted geometry for the reaction: a low impact parameter and a near collinear approach. A scenario of the collision could be as follows: following the first electron transfer, the newly formed Cl_2^- molecular ion is stretched rapidly as in the DIPR-DIP mechanism above. For collinear, low impact parameter trajectories, the stretching cannot be as rapid because of momentum conservation which pushes the nascent Ba^+Cl^- and Cl moieties together. Hence the close-packed inter-

mediate can transfer the second valence electron. It is transformed into $\text{Ba}^{2+}\text{Cl}^-\text{Cl}^-$ which dissociates very rapidly as $\text{BaCl}^+ + \text{Cl}^-$ because of the Coulomb repulsion between the two negative Cl^- ions. The same picture has also been proposed in $\text{Ba} + \text{Br}_2$ collisions [98].

The reactions of alkaline earth metal atoms with halogenated molecules, of which reaction (6) is an example, are sufficiently exoergic to lead to chemiluminescence [91]. The picture due to Menzinger for the branching to chemiluminescence is a broadside approach of Ba and Cl_2 in a near C_{2v} geometry. The outer harpoon forming Ba^+Cl_2^- with Ba^+ in its ground state $6s^2\ ^2\text{S}$ is forbidden for symmetry reasons (conical intersection between the covalent $\text{Ba} \cdots \text{Cl}_2$ and ion-pair $\text{Ba}^+ \cdots \text{Cl}_2^-$ states in C_{2v} geometry). This allows the system to reach an inner harpoon crossing where Ba^+ is formed in an electronically excited state. The resulting excited $\text{Ba}^{*+} \cdots \text{Cl}_2^-$ intermediate then decays into the chemiluminescent product BaCl . According to this scheme, chemiluminescence appears as due to the conservation of the electronic excitation of the positive ion as it goes from the ion-pair intermediate into the exit channel of the reaction.

Reaction products with a double ionic bond

Lee and co-workers distinguished three different classes for these reactions [90, 96, 102]:

- 1) Reactions going through a long-range transfer of the first valence electron, in a situation where the resulting molecular anion is stable. This is best illustrated by the $\text{Ba} + \text{NO}_2$ reaction.
- 2) Reactions with still a first long-range electron transfer, but in a situation where the molecular anion could promptly dissociate. The illustrative example will be the $\text{Ba} + \text{O}_3 \rightarrow \text{BaO} + \text{O}_2$ reaction.
- 3) Reactions involving a close collision for the first electron transfer. They will be exemplified by the $\text{Ba} + \text{H}_2\text{O}$ system.

Let us start with the first class of processes, which we illustrated by the reaction

A long-range electron transfer is possible in this reaction, as in alkali metal atom reactions. However, the resulting electron-transfer complex Ba^+NO_2^- does not correlate to the ground-state products BaO which has the structure $\text{Ba}^{2+}\text{O}^{2-}$. Moreover, the NO_2^- ion is stable and its dissociation into $\text{NO} + \text{O}^-$ is endoergic. Hence the Ba^+NO_2^- complex may survive for many rotational periods despite the availability of a very exoergic reaction channel. This is expected to dissociate after the transfer of the second valence electron of barium, which is probably hindered by an energy barrier.

This picture was first proposed by Lee and co-workers. It helps to interpret the angular and energy distributions of the product BaO observed in reaction 8, and shown as a 3D plot in Figure 5 [90, 96]. Panel D indicates that the reaction yields

Figure 5. (A) Newton diagram of the reaction, which was studied in a crossed-beam experiment. The other three panels are 3D plots showing the velocity and angular distribution of the product BaO in reaction (8). Panel D is the full signal, which is resolved into two components, a forward-backward symmetric component shown in panel B + a forward component shown in panel C. Adapted from Ref. [102].

mostly ground-state BaO with a forward-backward symmetry in the angular distribution. This suggests that BaO decays from a long-lived collision complex, in agreement with the mechanism proposed above. However, a direct forward product, which is believed to be vibrationally excited BaO(X), is superimposed on this dominant channel (see the slight forward-backward asymmetry in Figure 5 D, which is further resolved as the superposition of the forward component shown in panel C plus the long-lived complex component of panel B). An electron transfer is also conjectured to account for this channel, but in unfavorable geometries for the formation of a long-lived complex, for instance when Ba approaches very close to one of the oxygen atoms of NO₂. Figure 6 is a correlation diagram, which shows the two reaction channels accessible from Ba(¹S₀) + NO₂ collisions.

Besides reaction 8, formation of BaNO is also observed in Ba + NO₂ collisions. It is a minor reaction channel and the corresponding velocity-angle contour map reveals that the corresponding reaction channel goes through a very restricted range of collision geometries. It is believed to result from trajectories which are able to avoid the electron transfer, as this could happen when Ba approaches NO₂ on the N end of the molecule, off the C_{2v} axis. This kind of geometry is likely to maintain the system on a covalent surface and to promote the asymmetric stretching of the NO₂ molecule which is necessary for the formation of the BaNO product.

The reaction of barium with NO₂ has also a chemiluminescent channel, which was studied in a beam-gas arrangement [103]. The chemiluminescence originates from BaO(A ¹Σ⁺, A' ¹Π). The correlation diagram in Figure 6 indicates that both the direct and the indirect channel forming ground-state BaO may also lead to excited BaO through a non-adiabatic coupling. The product state distribution of the chemiluminescent product analyzed by Cheong and Parson is close to a prior distribution [103]. This suggests that the chemiluminescent product decays essentially

Figure 6. Correlation diagram for the reaction $\text{Ba}(^1\text{S}_0) + \text{NO}_2$. Adapted from Ref. [102].

from the long-lived complex, as it is waiting for the second electron transfer ultimately to form ground-state BaO.

The second class of processes also corresponds to a long-range transfer of the first valence electron, as in the reaction

but the complex Ba^+O_3^- formed in this case is very different from the Ba^+NO_2^- complex encountered in the previous example. The important point here concerning the dynamics of the subsequent reaction is the dissociation property of the negative molecular ion. Let us follow the simple dynamics considerations recalled in Section 2.3.1. Whereas the O^- production is endoergic from NO_2^- , it is exoergic from O_3^- . In the former case this has led to the existence of a persistent complex because NO_2^- was not going to dissociate spontaneously. On the contrary the complex had to wait for the second electron transfer before dissociating. No such delay is expected with O_3 and a spectator stripping character could be anticipated for the dynamics of the reaction. Nevertheless, one should not forget that the complex formed from a single electron transfer does not correlate to the ground-state reaction product. Hence the dynamics of the reaction cannot correspond purely to a spectator stripping reaction. It is therefore not surprising that the experiment reveals a mixed character of both a spectator stripping and a long lived complex reaction [96].

We switch now to the last class of reactions where a long-range electron transfer is not possible because the possible electron acceptor has a negative electron affinity. This is the case of water.

A crossed molecular beam study of $\text{Ba} + \text{H}_2\text{O}$ collisions by Lee and co-workers has shown that BaO is the major reaction product, even at collision energies well above the barrier of endoergicity for the formation of the BaOH product [90, 104]. This result precludes the formation of an intermediate where barium is inserted into an OH bond. On the contrary, it was interpreted on the ground of a concerted mechanism, with abstraction of the central O atom of HOH and simultaneous formation of H_2 . This process is induced by a very short distance ($< 2 \text{ \AA}$) electron transfer, and two points make it realistic. First, the valence electron of barium is transferred into the $4a_1$ orbital of water, which is antibonding with respect to both OH bonds. Second, the electron jump distance is close to the bond length of ground-state BaO , which has the structure $\text{Ba}^{2+}\text{O}^{2-}$. The system is therefore in a good position to transfer readily the second electron required for the formation of the BaO product at the same time as the H_2 molecule is formed. The kick of barium into water in near C_{2v} geometry, by stimulating the bending of the molecule, also favors the formation of H_2 .

In reaction with methanol, barium leads to the methoxide, and not to BaO . This is surprising at first glance since the barium + alcohol reaction should have a similar mechanism to the barium + water reaction. In fact, the reaction starts the same with a close collision between barium and methanol, but the concerted formation of the H-H bond in the water mechanism has no equivalent when H-O-H (water) is replaced by H-O-CH_3 (methanol). Its equivalent would be the concerted formation of H-CH_3 , which should go through a three-center transition state, and would necessitate the rotation of the sp^3 carbon to put it into position for bonding with the H atom leaving OH . This is very unfavorable and the H atom prefers to migrate, hence forming temporarily the insertion intermediate HBaOCH_3 , which decays to $\text{BaOCH}_3 + \text{H}$ [104].

The above two scenarios for the reactions with water and methanol not only are supported by the nature of the reaction products, but also account for the product angular and recoil velocity distributions observed experimentally. In particular, the concerted three-center elimination of H_2 implies a substantial bond rearrangement, which implies energy barriers in the entrance and in the exit valley of the reaction, hence resulting in a certain duration of the collision complex, in agreement with the observed forward-backward symmetrical angular distribution of the product BaO [104]. Interestingly, these scenarios are close to those encountered in the chemiluminescent reactions of alkaline earth metal atoms (Ca , Sr , Ba) with stronger oxidizing agents: H_2O_2 , $t\text{-BuOOH}$ and HNO_3 . A near-statistical distribution of the product energy states was observed, thus suggesting again that these products decay from a long-lived complex [103, 105].

2.3.4 Beyond the Harpoon Model: the HOMO/LUMO Matching to Describe Transition Metal Reactivity

The gas-phase chemistry of ground-state transition metals is much less well understood and has attracted far fewer studies than the reaction dynamics of alkali and alkaline earth metal atoms. Three reasons explain this situation. The first is experi-

mental. Owing to the refractory nature of most transition metals, it is difficult to generate the intense beams which are necessary for reaction dynamic studies. Second, the electronic structure of the transition metal compounds involves the participation of d electrons, which complicates tremendously the interpretations, especially because of the third reason: many oxidation reactions of transition metals are very exoergic, with the consequence that many product states are populated. Despite these difficulties, significant progress has been made in this field and three very recent achievements can be quoted: (i) the beam-gas investigation by Parson and co-workers of the chemiluminescent reaction between manganese and ozone [40], (ii) the work performed by Levy's group where the laser ablation of Mn and MnO₂ targets was employed to investigate the reactions $\text{Mn}(a^6\text{S}, a^6\text{D}_J, \dots) + \text{Cl}_2 \rightarrow \text{MnCl}^* + \text{Cl}$ in a beam-gas configuration [39], and (iii) the crossed beam study of Vetter et al. on the oxidation reactions of $\text{Ti}(a^3\text{F}_J, a^5\text{F}_J)$ atoms by O₂, NO and N₂O [106].

Reactions of transition metals with oxidizing molecules cannot be interpreted so simply on the basis of the harpoon model, even when considering reactions with a good oxidizing agent such as ozone or Cl₂. The ionization energy of the ground-state metal falls in the 7 eV range, which precludes a long-range electron transfer. For example, manganese has an ionization potential of 7.43 eV [89], hence the crossing between the covalent Mn + O₃ curve and the ion-pair curve occurs at a distance of 2.7 Å, which is only 1.6 times the equilibrium distance of the expected reaction product MnO (1.7 Å). Moreover, and for the same reason, reaction products such as MnO are largely covalent in nature [40]. Despite this, reactions such as

do proceed via an electron-transfer reaction, but not according to the simple harpoon model picture. In the case just mentioned, manganese is the donor and ozone the acceptor. This reaction was investigated by Parson and co-workers, whose interpretation is summarized in Figure 7 [40]. These authors suggested that the behavior of the system could be essentially adiabatic and interpreted based on the correlation of frontier orbitals (see Ref. [107] for an illuminating discussion of how electron transfers from HOMOs into LUMOs control reactions). A consideration of the electronic structure of the reactants and products suggests the picture called 'forward σ -donation' in the top left corner of Fig. 7. The sd_{z^2} hybridized orbital of Mn takes the part of the HOMO and, when manganese approaches perpendicular to the O₃ plane with the sd_{z^2} pointing toward a terminal O atom of O₃, this orbital overlaps the LUMO of ozone ($2b_1$), hence producing a bonding σ -orbital centered on the O atom and an antibonding σ^* -orbital centered on the Mn atom. This corresponds to a newly formed polar covalent Mn–O bond which is further strengthened by the back-donation a π -electron from the 2p π -orbital of the terminal O atom into the empty 3d π -orbital of manganese (see the middle panel of Figure 7. This results in a slackening of the O₂–O bond and energy is released as in the above-mentioned DIPR model (see Section 2.3.2) along the O₂–OMn bond, in agreement with the observed high product rotational excitation.

2.3.5 Multicenter Harpoon Reactions

These reactions were pioneered by Grice and co-workers who first addressed the reactivity of alkali metal dimers with halogen molecules [108–111]. These reactions are four-center harpoon reactions. They are interesting because of the possibility of two sequential electron jumps [112].

Let us take the collision $K_2 + Br_2$ as an example. The dominant reaction channels are

Chemiluminescent channels have also been observed in this type of reaction [113]. Reactions of alkali metal dimers with oxygen molecules have also been reported [114–116].

The electron jump forming $\text{K}_2^+ \cdots \text{Br}_2^-$ in the $\text{K}_2 + \text{Br}_2$ collision occurs at a 7 Å distance. The resulting complex has the biradical structure $\text{K}^* \text{K}^+ \text{Br}^- \text{Br}^*$ [108, 109, 111]. Its principal decay mode is the formation of the di-alkali metal complex $\text{K}^* \text{K}^+ \text{Br}^-$ because, as in alkali metal–halogen reactions, the excess electron of the Br_2^- moiety induces its dissociation. Most reactive trajectories lead to further dissociation of the complex to $\text{K}^* + \text{K}^+ \text{Br}^-$, which corresponds to the dominant channel of the reaction, i.e. process 11. The two other reaction channels require a second electron jump, hence forming temporarily $\text{K}^+ \text{K}^+ \text{Br}^- \text{Br}^-$. The bent geometry of the latter complex tends to produce two KBr molecules as in reaction 12, whereas its linear geometry leads to reaction 13.

A number of chemiluminescent studies of chemiluminescent multicenter reactions of transition metal dimers and trimers have been reported [117], namely

Reactions of Mn_3 have also been reported. The analysis of the observed emissions served essentially to unravel the complex spectroscopy of the manganese halides rather than investigating the dynamics of the corresponding reactions.

2.3.6 Harpoon Reactions with Surfaces

The harpoon model, in the simple form given in Section 2.3.1, has been used recently in a very different, although related, context to gas-phase reactions. It has been used to account for the observation of Cl^- ions embedded in a potassium surface when colliding a beam of Cl_2 molecules with the surface at suprathreshold energies (0.08–0.68 eV) [118]. A four step model is proposed. Its first step is the harpoon: at 4 Å from the surface, an electron is transferred from potassium to the antibonding orbital of Cl_2 , which dissociates to $\text{Cl} + \text{Cl}^-$, as in the gas-phase process. The differences from the gas-phase process are found in the next three steps where the metal surface transfers a further electron to the Cl moiety and emits an Auger electron. Similar experiments have also been done by colliding vibrationally excited SF_6 molecules with a barium surface [119] and CH_3I molecules with an Ag(111) surface [120].

More recently, N_2O molecules have been collided with a monolayer of Li on Rh(100). Two different reaction channels were observed. First, a direct reaction channel with an Eley–Rideal mechanism, i.e., an abstraction reaction that pro-

ceeds during the impact of the N_2O where harpooning is the key step that triggers the reaction. Second, an indirect reaction channel, which follows the Langmuir–Hinshelwood scheme where the reacting molecules are adsorbed on the surface with complete energy accommodation and thus a complete loss of the information on their initial orientation in the gas phase [121, 122]. As in the previous example, the gas-phase harpoon-like mechanism is invoked to account for the observed phenomena.

2.4 Effect of Changing the Internal State of the Reactants

Adding energy to a reactive system is, of course, a way to overcome a possible endoergicity. In a more subtle way this can also serve to pass an activation barrier placed somewhere along the reaction path. With this in mind, the addition of energy is expected to affect the dynamics of the reaction. If the reaction is direct and if the reactants do not have too many degrees of freedom, this effect could be different, whether the additional energy appears as translation, vibration or electronic excitation of the system.

One of the first attempts to compare the effect of different forms of energy on gas-phase reactions was done in a very general way by John Polanyi [70, 73]. When the reaction barrier is in the entrance or the exit channel of the reaction, translational or vibrational energy, respectively, is more efficient at promoting the reaction. These rules, known as *Polanyi's rules*, are not linked specifically to electron-transfer reactions. On the contrary, they were derived without reference to a specific reaction. As an illustration of these rules in an electron-transfer reaction, vibrational excitation of HCl gives easier access than translation to a late barrier in the $\text{K} + \text{HCl}$ reaction [123, 124].

In the context of this chapter, we shall focus on work where the additional energy deposited into the system directly affects the electron-transfer step and consequently changes the dynamics of the reaction.

2.4.1 Changing the Vibrational State of the Molecular Reactant

The geometry of molecular anions generally differs from that of the neutral molecule. For instance, N_2O^- is bent whereas the N_2O molecule is linear. This is one of the reasons why the vertical electron affinity of N_2O^- is negative. This is also the reason why bending excitation increases the electron affinity (EA) of the molecule. From Magee's equation (see Eq. 3), we know that the increase in EA results in a larger distance R_c for the harpoon. A larger cross-section is therefore expected. This effect has actually been observed semiquantitatively in the chemiluminescent reaction $\text{Ba} + \text{N}_2\text{O} \rightarrow \text{BaO} + \text{N}_2$ [125, 126]. The same effect was confirmed later in an experiment where the internal excitation of N_2O was carefully prepared [127]. It

should be noted that the full interpretation of the $\text{Ba} + \text{N}_2\text{O}$ reaction cannot rest on the simple harpoon model since barium is an alkaline earth metal atom with two valence electrons (see Section 2.3.3).

The dependence of the harpoon crossing radius R_c on the geometry of the molecules was pointed out a long time ago for the stretching of the C–I bond in CH_3I [128, 129] and appears as a major feature in the most recent mechanistic interpretation of the $\text{K} + \text{CH}_3\text{I} \rightarrow \text{KI} + \text{CH}_3$ reaction [69].

The same phenomenon has shown up as a very spectacular effect in a study by Kleyn and co-workers looking at collisions between cesium and O_2 at hyperthermal collision energies (25–100 eV) [130–133]. Let us consider the reaction

The following picture emerges from their illuminating work [131]. The initial electron transfer forms the anion O_2^- with the bond length of the neutral molecule, shorter than that of the anion. Hence the newly formed O_2^- is compressed and starts to oscillate with a period of 3×10^{-14} s. At the chosen collision energy, depending on the impact parameter, the collision time varies between 0.5 and 3 times the vibration period. As a result, there is a family of impact parameters where O_2^- is back in position to return the captured electron on the exit channel of the collision, but there is another family also, for which the electron return is impossible. This leads to oscillations in the angular distribution of the Cs atoms, which can be related to the vibrational period of O_2^- .

2.4.2 Electronic Excitation to Overcome an Endoergicity Barrier

Reactions of electronically excited atoms were investigated many years ago [134–137], and have been the subject of continuous efforts [91, 138–140]. Recent reviews cover the subject [42, 90, 141–143]. It is useless to review these studies again in a general way. We prefer to focus our attention on a limited number of studies which illustrate the various effects that electronic excitation can have on the reaction dynamics.

The first effect is simply energetics. Electronic energy corresponds in general to a large amount of energy (up to several eV), which is deposited in one step into the system. This is often more than enough to satisfy the energy requirement of a substantially endoergic reaction. A large number of studies illustrate this point. For a large part, they are reviewed in the papers quoted above.

$\text{Na} + \text{HF}$ is one of the systems where electronic excitation promotes the reaction. In this case, $\text{NaF} + \text{H}$ is formed. This reaction has been studied both in the gas phase and in van der Waals complexes, and we reserve its discussion to the section on van der Waals complexes (Section 2.6). We focus our attention here on a related system, the reaction

Owing to its large endoergicity, it needs laser excitation to be turned on.

Reaction 16 was first laser induced by Happer and co-workers in a cell experiment under a multi-collision regime, which allowed, spectacularly, the product CsH to condense as powder, the so-called *laser snow* [144]. The dynamic picture of this reaction has emerged from a series of studies by Vetter and co-workers using a crossed-beam machine where cesium was excited to both the levels $6d\ ^2D$ [145] and $7p\ ^2P$ [146–150]. The most interesting result concerns the reaction dynamics of cesium in the $(7p\ ^2P_{1/2})$ level, which was interpreted after *ab initio* potential energy surface, semi-classical and quantal dynamics calculations [151–153]. The reaction of cesium in the $8p\ ^2P$ and $9p\ ^2P$ Rydberg levels with hydrogen molecules has also been studied [154].

We now summarize the results of Vetter and co-workers on the reaction dynamics of $Cs(7p\ ^2P)$ [146–150]. Although molecular hydrogen has a negative electron affinity, the reaction appears as an harpoon reaction with an electron-transfer distance of about 4 Å. Despite this significantly large distance, the measured reactive cross-section is very small, $0.6\ \text{\AA}^2$. This effect is due to the large electronic excitation needed to overcome the endoergicity barrier. The $7p\ ^2P$ level is indeed higher in energy than many other cesium levels, namely the $6s\ ^2S$, $6p\ ^2P$, $5d\ ^2D$ and $7s\ ^2S$ levels. Hence the attractive ion-pair surface $Cs^+H_2^-$ crosses the covalent surfaces correlating to these lower levels, and more than 90 % of the trajectories end up on these states after back-transfer of the electron to cesium rather than leading to dissociation of H_2^- and forming the reaction product Cs^+H^- . This example is interesting because the large electronic excitation needed to open the reactive channel also opens non-reactive quenching processes which enter in competition with the reactive channel.

The similar system $K^* + H_2 \rightarrow KH + H$ has also been studied, with similar information on the reaction dynamics [155, 156]: the reaction of electronically excited potassium follows a collinear geometry, producing KH via the ion-pair intermediate K^+H^-H . Very interestingly, this reaction is state specific: $K(7s\ ^2S)$ leads to reaction, whereas $K(5d\ ^2D)$ does not. We shall come back to this important question later.

Before leaving this section, let us make a short digression to the mechanism invoked above, where the forward and back electron transfer between cesium and H_2 is responsible for the quenching of the electronic excitation of cesium. This mechanism was proposed a long time ago to account for the quenching of the first electronic state of sodium by collision with nitrogen, a non-reactive molecule. This model, plus a few related ones, have been reviewed by Schermann et al. [139]. According to the model, the covalent potential curves describing the excited and ground states of the $Na + N_2$ system are coupled together by the ion-pair curve $Na^+N_2^-$. This model was proposed originally by Jerre and Nikitin [157]. It was rediscovered by Bauer et al. [158] and was further developed by Gislason and Sachs [61, 159]. It has been used widely to account for quenching experiments by Hertel's group [160] and was put eventually into the more correct form of the *bond-stretch* model. Molecules such as N_2 and H_2 do not accept an electron easily, hence the electron transfer on the molecule is only partial and progressive along the entrance channel of the collision. It is accompanied by stretching of the molecule which also results in coupling between the electronically excited state of the system and its ground state, hence leading to quenching [161].

2.4.3 Effect of Electronic Excitation on the Reaction Dynamics

The idea behind these studies is that electronic excitation of one of the reactants certainly affects the dynamics of the reaction and in some cases allows one to control the outcome of the reaction. An important aspect of electronic excitation is the possibility of selecting the potential energy surface on which the reaction is initiated, just by exciting the reactants to states of various symmetries. In other words, the motivation for studying the excited-state reaction dynamics comes from the anticipation that the dynamics of the reaction are determined not only by the amount of energy which is available in the system, but also by the nature of the excited potential energy surface on which the reaction proceeds. Of course, this can occur only if one of two conditions is met: the electronic energy deposited in the system is not randomized too rapidly as a hot ground state of the system, or the electron-transfer step does not connect the system directly on the ground-state surface of the exit valley.

Dramatic effects of electronic excitation on the reaction mechanisms have been demonstrated in several cases. One of the first reported examples must be recalled here also as it falls outside the scope of this chapter. Electronically excited $O(^1D)$ is much more reactive than ground-state $O(^3P)$ and inserts into the C–H bonds of methane [162]. Similar state specificity in the reactivity has also been encountered in electron-transfer reactions and seems to be the rule in light systems. Its origin has been explored systematically in alkali and alkaline earth metal atom reactions. Before discussing some of the studies, it is appropriate to survey a much simpler situation where electronic excitation affects the dynamics of the reaction just by changing the location of the electron-transfer region.

Dynamic effects associated with the change of the electron-transfer distance

This effect is best viewed in single harpoon reactions such as those of alkali metal atoms with halogen-containing molecules discussed in Section 2.3.1. A series of studies conducted in a crossed-beam experiment by Lee's group at Berkeley have demonstrated how the electronic excitation of sodium affects the dynamics of these reactions.

The reaction $K + CH_3I \rightarrow KI + CH_3$ has been revisited very recently [69]. Let us start our discussion with another reaction of the same family:

This is a classical rebound reaction. When sodium is in the ground state, 84 % of the reaction product NaBr is scattered in the backward hemisphere. This phenomenon arises from two factors: a close approach distance for the electron transfer to proceed, and a *steric factor*, where sodium must approach the Br end of CH_3Br to bounce back as NaBr. If approaching the wrong end of CH_3Br , sodium does not react. This leads to the concept of the *acceptance angle* for the reaction [163].

When exciting sodium electronically to the $3p^2P$ and $4d^2D$ levels, the reactive cross-section increases, the center-of-mass angular distribution widens, but the re-

action still proceeds via the rebound mechanism [the backwards scattered fraction is 79 % for reaction of $\text{Na}(4d\ ^2D)$]. This has been interpreted as the relaxation of the steric factor and an opening up of the acceptance angle [164]. The origin of this effect is clear when following the recent interpretation of the acceptance angle given for the reaction $\text{K} + \text{CH}_3\text{I} \rightarrow \text{KI} + \text{CH}_3$ [69]. The assumption that the electron transfer which initiates the reaction is localized is only a first approximation. The more correct picture with a molecule such as CH_3I , which does not have a large positive electron affinity, is given by the *bond-stretch* model considered at the end of Section 2.4.2. A partial and progressive electron transfer initiates the elongation of the molecule, but importantly for the following, elongation of the C–I bond takes time. This makes the $\text{K} + \text{CH}_3\text{I} \rightarrow \text{KI} + \text{CH}_3$ reaction mimic a concerted reaction where the old bond stretches as the new bond begins to form. The stereodynamics of the reaction and, in Ref. [69], its dependence on the collision energy, stem from the ease of the final electron transfer. Of course, the more the $\text{CH}_3\text{–I}$ bond has had time to elongate during the early stage of the reaction, the easier is the final electron transfer which promotes the reaction, the longer is the distance at which it occurs and the less restrictive are the geometry requirements which allow the final electron transfer. In other words, a change in the partial electron transfer, which gives more time for the C–I bond to stretch, is expected to widen the acceptance angle of the reaction.

With this model in mind, the observation recalled above of the effect of increasing the electronic energy of sodium in the $\text{Na} + \text{CH}_3\text{Br} \rightarrow \text{NaBr} + \text{CH}_3$ reaction becomes clear. Since the excited orbitals of sodium are increasingly more diffuse on switching from $3s\ ^2S$ to $3p\ ^2P$ and $4d\ ^2D$, the first partial electron transfer occurs at larger and larger distances and allows more time for the CH_3Br molecule to stretch. Hence the final electron transfer is expected to be possible at a larger distance than simply deduced from the sole use of Magee's equation (see Eq. 3). At the same time, the steric requirements for the reaction are also expected to relax, in agreement with the experiment.

Opposite to rebound reactions is the reaction $\text{Na} + \text{Cl}_2 \rightarrow \text{NaCl} + \text{Cl}$ which proceeds via the spectator stripping mechanism. In this case, the crossing between the nonreactive covalent Na–Cl_2 curve and the Na^+Cl_2^- ion-pair curve, which promotes the reaction, occurs at a large distance ($R_c = 5.22\ \text{\AA}$, when using the chlorine adiabatic electron affinity in Magee's equation). This distance increases to $22.3\ \text{\AA}$ when sodium is excited to the $3p\ ^2P$ level. One would expect an increased reaction cross-section, but this is not observed because electron transfers at such large distance are inefficient. The overlap between the sodium HOMO and the Cl_2 LUMO is very small at these distances. As a result, when the crossing radius increases substantially, there is only a small effect on the dynamics of the reaction [164, 165].

The reaction

is very interesting because the dynamics of the reaction change completely when sodium switches from the ground state, where the reaction is endoergic, to $3p\ ^2P$ and either $4d\ ^2D$ or $4s\ ^2S$.

Excitation of sodium to the $3p\ ^2P$ level enhances tremendously the reaction cross-section and leads to a backscattered product with a broad velocity distribution. The qualitative agreement of the observed velocity and angular distribution of the NaCl product with fits by the DIPR-DIP model allows one to draw two conclusions: first, a near-isotropic distribution of the HCl molecule at the moment of the electron jump, with however a slight preference for the $\text{Na} \cdots \text{Cl}-\text{H}$ approach; and second, a partial breakdown of the basic DIPR-DIP assumption, which separates the breakage of the H-Cl bond from the formation of the Na-Cl bond. This suggests a concerted reaction (as above in the $\text{Na} + \text{CH}_3\text{Br}$ reaction), essentially because the electron jump distance is not very large (3.7 \AA). Additionally, the fact that the NaHCl system is close packed at the transition state, rather like a compressed spring, explains also why a lot of the energy release goes into translation after the reaction [166].

Excitation of sodium to the $4d\ ^2D$ and $4s\ ^2S$ levels, which are ca. 4.2 eV above the ground state, changes drastically the dynamics of the reaction. The electron-jump distance moves further away (ca. 8 \AA) and the system is no longer close packed at the transition state. As a result, although the system contains 2 eV more energy, the translational energy release between the products is smaller than in the $\text{Na}(3p\ ^2P)$ reaction. Most of the excess energy shows up as vibrational excitation of the product NaCl. Despite this, the reaction does not follow the spectator stripping mechanism. The product NaCl is mainly backward scattered [165, 167], bringing evidence for this continuous e-transfer.

State selectivity in alkali metal atom reactions

State-specific reactions of excited alkali metal atoms have been encountered a number of times. We have mentioned already the $\text{K} + \text{H}_2 \rightarrow \text{KH} + \text{H}$ reaction which is turned on by excitation of potassium to the $7s\ ^2S$ level (ca. 3.7 eV above the ground state), and not by the excitation to the $5d\ ^2D$ level, although it is only 0.01 eV below the $7s\ ^2S$ level [155, 156]. Such a change in reactivity is, of course, linked to the different potential energy surface on which the reaction is promoted, but owing to the equivalent energy of the $7s\ ^2S$ and $5d\ ^2D$ levels the difference in reactivity is connected with orbital symmetry.

Another striking example is provided by the $\text{Na} + \text{O}_2 \rightarrow \text{NaO} + \text{O}$ reaction, which is endoergic by 2.5 eV. Excitation of sodium to the $3p\ ^2P$ level provides the system with 2.1 eV electronic excitation, and the reaction could become possible with the help of translational energy. However, no such reaction is observed. The NaO product is observed only at a sufficiently high translational energy when sodium is excited with ca. 4 eV electronic energy in the $4d\ ^2D$ level [168]. In contrast, the $5s\ ^2S$ level, which has approximately the same energy, does not lead to reaction.

The nonreactivity of $\text{Na}(3p\ ^2P)$ finds a fairly simple explanation when the stability of the O_2^- ion is taken into account. Electronic excitation of Na to $3p\ ^2P$ actually promotes the formation of the intermediate Na^+O_2^- , but when the negative ion is formed in its ground state $X^2\Pi_g$ it does not dissociate spontaneously and the Coulomb field due to the Na^+ core is not enough to tear it apart. The only possibility

open for the intermediate $\text{Na}^+\text{O}_2^-(X^2\Pi_g)$ is to back-transfer the electron from O_2^- to Na^+ and to dissociate as $\text{Na} + \text{O}_2$. The temporary formation of the Na^+O_2^- intermediate resulted in this case in quenching of the electronic excitation of sodium. Presumably the formation of the NaO product is observed when the electron transfer from Na to O_2 forms the negative molecular ion in the dissociative excited state $A^2\Pi_u$ [169, 165, 170]. For this to occur, long-range electron transfer has to be avoided and the reaction proceeds only at restricted geometries and state symmetries. This could be the explanation of why the $4d\ ^2D$ level is reactive, and not $5s\ ^2S$. Again, orbital symmetry is seen to play a role in reaction dynamics. The control of chemical reactions by orbital symmetry is a very important issue in stereodynamics. It is the subject of Section 2.5 and is invoked in Section 2.6.1.

Interestingly, the necessity to transfer the electron to an excited O_2^- orbital for breaking the O–O bond has also been invoked in other circumstances when investigating the $\text{Na}_2 + \text{O}_2$ reaction [116].

Changing the reaction mechanism by changing the PES initiating the reaction

The two previous sections have shown that the largest changes in the reaction dynamics are to be expected when the electronic excitation added to the system moves the electron-transfer distance from a close-packed geometry where the harpoon mechanism is hardly applicable to distances at which the access to the electron-transfer region is easy. Similarly, when turning to reaction implying a double harpoon, the most dramatic changes in the reaction mechanism are expected for systems like $\text{Ba} + \text{H}_2\text{O}$ where the first electron transfer occurs at a short distance (see Section 2.3.3). This is confirmed by experiment. Whereas ground-state barium leads essentially to the product BaO on reaction with water, electronically excited barium, in either the $6s5d\ ^1D$ or the $6s6p\ ^1P$ level, leads to BaOH as reaction product [104, 171, 172]. This finds an easy interpretation within the framework provided by the double harpoon mechanism given in Section 2.3.3. Formation of BaO in the ground-state reaction has to wait for the second electron transfer in order to have its correct structure $\text{Ba}^{2+}\text{O}^{2-}$. Since the first electron jump occurs in a closed-pack geometry, the system is readily in position for the second valence electron of barium to transfer. The reaction forming BaO is thus of concerted nature. Promotion of one valence electron of barium to the $5d$ or the $6p$ orbital favors a longer range electron transfer. The system is then far from the favorable geometry for the second electron transfer. The weakly bonded H atom of the $\text{Ba}^+\text{H}_2\text{O}^-$ complex therefore has time to migrate and form the insertion intermediate $\text{H}-\text{Ba}-\text{OH}$, which dissociates to $\text{BaOH} + \text{H}$ [104]. The reaction paths corresponding to reaction of the ground-state $6s^2\ ^1S$ and the excited-state $6s5d\ ^1D$ of barium are shown as a correlation diagram in Figure 8.

A similar correlation diagram can be drawn to interpret the exclusive observation of BaOH chemiluminescence in the reaction of $\text{Ba}(6s6p\ ^1P)$ with water [172]. Here again, the reaction of excited barium can be explained by H-atom migration and formation of the intermediate HBaOH . This mechanism definitely carries some generality since it has been used also by Oberlander and Parson to account for re-

Figure 8. Correlation diagram for the reaction $\text{Ba} + \text{H}_2\text{O}$. The shaded areas indicate the uncertainties in energies of the collision complexes. Solid and dashed lines show the dominant and minor reaction paths, respectively. Adapted from Ref. [104].

actions of laser-excited calcium and strontium atoms with water and alcohols [173]. Related reactions of alkaline earth metal atoms with peroxide molecules have also been investigated by Parson's group, but the reaction mechanism differs since barium seems to insert into the O–O bond of the peroxides [103, 105].

The reactivity of excited alkaline earth metal atom reactions has attracted considerably more attention than reported above. Among the work that we shall not review here we must mention the investigations of Dagdigan and co-workers who explored the spin–orbit effects on the reactivity of metastable calcium and barium [174–181]. For example, significant differences in reactivity were observed between the three components $J = 0, 1$ and 2 of $\text{Ba}(6s5d\ ^3\text{D}_J)$. Spin–orbit effects have also been observed as a drastic change of reactivity between $\text{Cs}(7p\ ^2\text{P}_{1/2}) + \text{H}_2$ and $\text{Cs}(7p\ ^2\text{P}_{3/2}) + \text{H}_2$ [150]. Gonzalez Ureña's group has also contributed considerably to unraveling the reactivity of excited alkaline earth metal atoms, especially with halogen-containing molecules [37, 38, 182–187]. Part of this work is recalled in Section 2.6. Finally, the same kind of systems have also been investigated by the groups of Husain [188–190], Kowalski [41, 191–193], Lou [86, 194–196], Menzinger [197, 198] and Stolte [199, 200].

Conservation of the ion core electronic configuration

Work performed by the groups of Levy [39, 201–207], Parson [208, 209] and Sadeghi [210, 211, 212, 213, 214] have drawn attention to reactions of electronically excited multivalent atoms. These groups investigated reactions of copper and manganese atoms with halogen and halide molecules. Again, these reactions are well interpreted on the basis of the harpoon model, but in this case, owing to the variety of electronic levels of the halide product that may be excited, the interpretation implies a hierarchy of inner electron transfers. This question has been examined in

detail for reactions of Mn and $\text{Mn}^*(a^6D_J)$ with Cl_2 [39], SF_6 [205] and SiCl_4 [206]. The situation turns out to be very complicated because the covalent and the ion-pair curves corresponding to $\text{Mn}^*(a^6D_J)$ and $\text{Mn}^{+*}(a^5D_J)$ are split into several components by the interaction with the molecular partner, allowing a number of crossings at different approach distances and energies [205].

It is simpler for our present purpose to consider the reactions [210, 211, 214, 208]

The point which draws our attention here is the very strong increase in the CuF chemiluminescence when Cu switches from the ground-state $3d^{10}4s^2S$ to the excited-state $3d^94s^2^2D$.

Sadeghi and co-workers first pointed out that the electronic configuration of excited CuF is essentially $\text{Cu}^+(3d^94s)\text{F}^-$, and that it resembles to that of the excited ion pair $\text{Cu}^+(3d^94s) \cdots \text{F}_2^-$. This ion pair is thus likely to correlate to the excited-state product. Conversely, the ground-state ion pair $\text{Cu}^+(3d^{10}) \cdots \text{F}_2^-$ is likely to correlate to the ground-state product of dominant configuration $\text{Cu}^+(3d^{10})\text{F}^-$. This leads to the potential energy diagram shown in Figure 9. As suggested by Sadeghi and co-workers, the harpoon process in the entrance channel of the reaction corresponds to the minimal electronic rearrangement when ground-state $\text{Cu}(3d^{10}4s^2S)$ transfers one of the 4s electrons to molecular fluorine, thus forming the ground-state ion pair. Similarly excited $\text{Cu}(3d^94s^2^2D)$, by transferring one 4s electron, forms the excited ion pair, which correlates to the excited-state product. This correlation helps

Figure 9. Potential energy diagram for the $\text{Cu} + \text{F}_2$ reaction. The circles indicate the crossing regions where the electron jump takes place. Adapted from Ref. [210].

in understanding why the electronic excitation of copper increases tremendously the chemiluminescence yield of the reaction [208, 210, 211, 214]. Conservation of the electronic configuration of the metal ion core along the reaction path thus appears important in the branching to chemiluminescence.

2.5 Stereodynamics of the Electron Transfer

Stereodynamics is focused on the dependence of forces on reactant orientation (or alignment) in the course of chemical reactions [15]. One of the ideas behind this is to use these forces to control chemical reactions [17]. Continuous efforts have been made toward this goal in recent years, and the ultimate step at the moment is coherent control [215]. We shall not consider these questions here. We prefer to follow a second idea behind stereodynamic studies, which is more simply to refine our understanding of how reactive systems access the transition state region of the reaction.

We have encountered in several places in this chapter that orbital symmetry plays a role in the reactivity of excited-state metals. Such symmetry effects are best observed in vector correlation experiments where the effect of orienting and aligning reactants is explored systematically and correlated to the angular distribution of the reaction products [216–220].

Two routes have been followed in reaction stereodynamics. One is to orient a molecular reactant in space and see how the reaction cross-section varies with the molecular orientation. This direction has been pioneered in molecular beam experiments using focusing of an electric hexapole field to control the molecular orientation [221–223a]. Numerous studies have applied this technique to electron-transfer reactions of alkaline-earth atoms [223b]. This technique is now complemented by the so-called *brute force* technique, where polar molecules are oriented in extremely strong electric fields [83].

The other route applies when the reactivity of laser-excited species is to be studied. It is then possible to polarize the excited orbital and observe how this polarization affects the dynamics of the reaction. This was first demonstrated by observing the alignment-dependent chemiluminescence in reactions of aligned $\text{Ca}(4s4p\ ^1\text{P})$ with halogen-containing molecules [224, 225]. This work will serve to rationalize the branching to chemiluminescence observed in reactions induced in van der Waals complexes (see Section 2.6.1). It has been extended very recently to other molecular reactants [196].

There is a bridge between the two routes when bimolecular collisions are initiated by a prior photodissociation to produce aligned reactants [226].

Within the framework of this chapter, a section on stereodynamics must focus on the heart of harpoon reactions: the electron transfer itself. Hence we review studies which directly inform on the extent to which the electron transfer is affected by the relative polarization of the donor (HOMO) and acceptor (LUMO) orbitals.

The electron-transfer step can almost be isolated when observing ion-pair for-

mation in hyperthermal collisions. Such experiments have been done recently by Brooks and co-workers [227–229]. For example, a beam of potassium atoms has been crossed with a beam of acetonitrile molecules which had been oriented spatially prior to collision. Collision energies of 5–30 eV are sufficient to separate the charged species after the collision if a K atom has transferred its valence electron to the acetonitrile molecule. The most abundant negative ion, CN^- , is preferentially formed upon attack at the CN end of the molecule, whereas the CH_3CN^- ion is observed at large collision energies with attack at the CH_3 end of the molecule. These results have been rationalized by assuming that the CN^- production results from an initial electron transfer into the π_{CN}^* LUMO (located on the CN group), followed by migration into the σ_{CC}^* . Conversely, formation of CH_3CN results from the electron transfer into a σ_{CH}^* LUMO at the other end of the molecule [229].

Such preference in molecular orientation for electron transfer certainly should show up in the reaction dynamics, especially when seeking to direct reactions. This was exemplified for the first time in the reaction of sodium with a different molecule [230]:

This reaction was studied using a crossed-beam apparatus. It was found that the favorable alignment of the D orbital of sodium varies only slightly with the scattering angle of the product NaCl. The best geometry is when the d_{z^2} orbital of sodium is aligned along the relative velocity vector of the collision.

In interpreting these experiments, the following difficulty must be noted. The orbital preparation is performed in the laboratory reference frame at infinite separation between the reactant, and might be different from the actual orbital alignment in the molecular frame, at finite separation between reactants when the system is close to the electron-transfer region. This difficulty refers to the concept of *locking radius*, involving the locking of orbitals to the rotating molecular frame in the course of a collision [231, 232]. With this in mind, it has been concluded from experimental observations that the reaction $\text{Na}(4d^2D) + \text{HCl} \rightarrow \text{NaCl} + \text{H}$ goes through a long-range electron transfer, and that the Na–HCl axis dominates over the Cl–H axis in determining the most favorable alignment angle. In other words, the d_{z^2} orbital of sodium just needs to be pointing at the HCl molecule for the reaction to proceed, but the Na, Cl and H atoms do not need to be collinear at the transition state [230]. Of course this picture complements that drawn in Section 2.4.3 when discussing reactions of electronically excited sodium.

Measuring the polarization of the reaction product is also an important issue in stereodynamics. A lot of the activity in this field concerns the reactivity of alkaline earth metal atoms since the corresponding reaction products are easy to probe by optical techniques. A full account of methods to measure product alignment and orientation in bimolecular collisions has been given by Orr-Ewing and Zare [18]. Such measurements, with the help of simple models such as the DIPR-DIP model considered Section 2.3.2, give insight into the shape of the reactive system at the moment where forces are released [86, 87, 184, 195, 233, 234].

2.6 Van der Waals Complexes: a Tool to Explore the Potential Energy Surface in the Electron-transfer Region

We now present a new tool to investigate in further detail the potential energy surfaces for electron transfer, especially those involving excited states of the reacting metal. One could think that the models introduced in the previous sections, namely the double harpoon originally described by Menzinger [91, 92] and the DIPR-DIP model refined by Zare and co-workers [81], are oversimplified. Instead, the present section confirms their simplicity and predictivity in explaining the branching of excited-state metal reactions to luminescent products.

The preceding sections have emphasized the role of the relative orientation of the reagents: geometric orientation or orbital orientation of an electronically excited metal with respect to the collision axis. This applies to excited metal orbitals with p or d symmetry and has been termed polarization effects, where in the laboratory frame the polarization of the light aligns the excited orbital. Instead, reactions initiated within the molecular 'body fixed frame', within a van der Waals complex formed by the reagents, offer a powerful way to study this problem of the relative orientation of the excited orbital of the metal, directly in the frame of the reactants. When an electron-transfer reaction is initiated in the complex by light, the relative orientation of the orbital with the approach coordinate of the reagents is dictated by the orbital symmetry of the accessed state and in this electronic state the reagents have a fixed, specific orientation. The resulting bimolecular excited-state reactions promoted by optical excitation of a van der Waals complex formed by the reactants are accessed directly via the excited reaction complex. This allows the direct spectroscopic investigation of the reaction surface when occurring in the excited state, through the laser-induced spectra of the reaction. This was first shown by Jouvét and Soep [47–49]. Also, it must be emphasized that in the perspective of a half-collision the reactants are prealigned and this allows stereodynamic studies, as shown by Wittig and co-workers [50]. The reactions within van der Waals complexes are also closely related to laser-assisted collisions, as developed for chemical reactions by Setser and co-workers [235–237], where the reaction complex is attained from the dissociative collision pair in the ground-state complex instead of the bottom of the potential well of the interaction van der Waals potential. In a scheme later called laser photoassociation [238], the colliding ground-state collision pair is transferred into the quasi-bound potential domain of the reacting excited complex. The studied systems involve harpoon-type reactions in xenon–halogenated compounds. In this manner, laser-assisted reactions have been performed in low-pressure gas mixtures of Xe with Br₂, CCl₄, CCl₃Br, CCl₂Br₂ and I₂. The products are XeCl(B, C), XeBr(B, C) or XeI(B, C) following two-photon promotion to the reactive ion-pair potentials. The utilization of a two-color scheme enhances the two-photon, laser-assisted reactions because of better match with an intermediate state of the reagent molecule. In this work, interesting preferences in the reactions with mixed halogenated compounds were found for the final excited-state products.

A typical van der Waals complex experiment consists in recording the reactive signal as a function of the wavelength of the laser inducing the reaction. The re-

sulting spectra are called *action spectra*. They usually appear as a series of broad bands, the spacing (vibrational) of which characterizes ‘modes’ on the reaction surface that are weakly coupled to the reaction coordinate, the *perpendicular modes*. Excitation along the reaction coordinate does not produce any vibrational structure in the action spectrum, because there is no bonding along this coordinate. Such spectra are intrinsically diffuse and analogous to bound-free spectra in molecules. In turn, the breadth of the diffuse perpendicular bands is related to the dynamics of the reaction through the kinetics of departure from the Franck–Condon accessed region on the surface. This spectroscopy is similar to that of bound molecules for the so-called perpendicular modes where the observed vibrations are directly related to an equivalent potential surface. This can be done by either Franck–Condon overlap [49, 239, 240] or wavepacket calculations [241–243]. Hence the explored region in the reaction on the reaction surface depends on the Franck–Condon allowed window from the ground state.

The van der Waals initiated reaction explores ideally excited-state harpoon reactions. The latter occur at intermolecular distances in the range 3–10 Å, a region which is Franck–Condon accessible from ground-state van der Waals complexes, whose equilibrium distance is typically $R = 3\text{--}4\text{ Å}$.

2.6.1 Local Excitation and Subsequent Electron Transfer

Excited mercury chemiluminescent reactions

The first example of such reactions is the reaction of excited mercury, $\text{Hg}(6s6p\ ^3P_1) + \text{Cl}_2$ [47], in which the crossing seam of the neutral and ionic [correlating with $\text{Hg}(6s\ ^2S) + \text{Cl}_2^-$] surfaces, can be directly observed. The excited-state mercury atom becomes open shell with an ionization energy close to 5 eV, almost a sodium atom, and the resulting ionic covalent crossing occurs at 4 Å! The schematics of the reaction and observation conditions are described in Figure 10, where the reaction has sufficient energy to produce excited-state products $\text{HgCl}(\text{B}\ ^2\Sigma^+)$. Thus, the laser scans the potential energy surface of the reaction and produces chemiluminescent

Figure 10. Potential energy diagram of the reaction of Hg with Cl_2 along the $R_{\text{Hg}-\text{Cl}_2}$ coordinate. The excitation Franck–Condon region is reproduced and the positions of energy levels of the HgCl product are reproduced at scale, together with the insertion product ClHgCl levels. This latter product is not observed. Adapted from Ref. [47].

Figure 11. Action spectrum monitoring the HgCl emission while scanning the laser inducing the reaction in the region of the Hg resonance line. The spectrum is broad and falls off sharply after this line. The simulation is obtained using the potential in the inset and the ground-state wavefunction as pictured in the diagram. The contribution to the spectrum comes essentially from the $|-\rangle \rightarrow |+\rangle$ branch of the potential in the inset. Adapted from Ref. [49].

products that are detected via the HgCl B–X emission. The resulting action spectrum appears in Figure 11, where a broad continuum of width 1000 cm^{-1} falls abruptly, shortly after the mercury line. This indicates that the transition relates to the local excitation of the mercury joining on to the neutral asymptote correlating with $\text{Hg}(6s6p\ ^3P_1) + \text{Cl}_2$. Therefore, the state accessed by the excitation laser has a compound character with a mixing coefficient that depends on $R_{\text{Hg-Cl}_2}$, the mercury–chlorine distance. The mixing coefficient depends simply on the energy gap $\Delta E(R)_{\text{IC}}$ between the covalent and ionic potentials:

$$\frac{H_{\text{IC}}}{\Delta E(R)_{\text{IC}}} \quad (22)$$

where H_{IC} is the ionic–covalent matrix element. There results a mixed adiabatic potential represented in the inset in Figure 11. In the hypothesis (verified) that the reaction is fast, all excited complexes will have reacted and the intensity of the spectrum has been shown to be proportional to the Franck–Condon factor connecting the ground-state complex with the locally excited state accessed by optical excitation at each energy:

$$(\langle \Psi_{\text{Hg-Cl}_2} | \Psi_{\text{Hg}^+-\text{Cl}_2(E)} \rangle)^2 \quad (23)$$

The potential $E(R)$ corresponds to the mixed ionic covalent state and takes into account the R -dependent coupling via the ionic–covalent matrix element H_{IC} . In simulating the experimental curve in Figure 11, this coupling was found to be small 0.1 eV , which is unusual for this type of allowed reaction. This small value results from the geometry of the reacting molecule, T-shaped as produced by the Franck–Condon excitation of the ground-state Hg–Cl₂ complex, T-shaped. The T-shaped geometry with C_{2v} symmetry of the excited reacting complex has an unfavorable overlap for the electron transfer [49] from a $6p\sigma$ mercury orbital to the

antibonding orbital of the chlorine for symmetry reasons. In this experiment, no evidence was found for the observation of the other orbital orientation.

This experiment allowed the direct exploration of the radial part of the excited-state electron-transfer surface, here at the transition-state level and also partially in the exit valley. It has also provided further evidence of the angular dependence of the electron transfer which is addressed in the following example. This example does not take into account the correlations with excited ionic surfaces accessed by 6s electron transfer because these surfaces lie at too high energy in the case of mercury. This type of electron transfer will be described in the following section.

Ca–HX excited-state reactions

The reaction of excited-state calcium with hydrogen chloride had been considered by Bernstein et al. [15] as an example where an excited-state body-fixed orientation could be achieved, in relation with the polarization collision experiments of Rettner and Zare [225]. The reactions of locally excited calcium, in $4s4p\ ^1P_1$ and $4s3d\ ^1D_2$ states, within complexes with the hydrogen halides HF, HCl, HBr and HI have been observed within the body frame of the excited van der Waals complex, while detecting the excited-state reaction products [243–245] by luminescence or the ground-state products by laser-induced fluorescence (in the case of Ca–HCl) [246]. Also, full collision experiments conducted by Gonzalès-Ureña's group [233, 247] have yielded interesting comparisons. In the full and half collisions of excited Ca with HX, the open decay channels are:

- $\text{Ca}^{**} + \text{HX} \rightarrow \text{Ca}^* + \text{HX}$: electronic relaxation of Ca, where Ca^{**} represents the $4s4p\ ^1P_1$ and $4s3d\ ^1D_2$ states and Ca^* one of the lower calcium states.
- $\text{Ca}^{**} + \text{HX} \rightarrow \text{CaX} + \text{H}$: ground-state product formation.
- $\text{Ca}^{**} + \text{HX} \rightarrow \text{CaX}(\text{A}, \text{B}) + \text{H}$: excited-state product formation. Notably the only system that comes at threshold for the production of the A and B states is the $\text{Ca}(4s3d\ ^1D_2) + \text{HF}$ system.

The ground and excited states A, B of the CaX product are observed to be the essential outcomes of the half collision, where electronic relaxation does not seem to be able to compete. Detecting excited- or ground-state products yields expectedly different results.

Local excitation of the metal

Here we encounter a new situation: the local excitation of the calcium chromophore from the ground-state $\text{Ca} \cdots \text{HCl}$ complexes transfers the complex in a strongly attractive van der Waals potential amidst two electron-transfer regions: the transfer of the 4p or 3d electron at long $R_{\text{Ca} \cdots \text{HX}}$ distances to form $\text{Ca}^+(^2\text{S})\text{--HX}^-$ and at short distances the transfer of the 4s electron to the excited $\text{Ca}^+(^2\text{D})\text{--HX}^-$. Both crossings will differ from one halogen to the other owing to the variation in the electron affinity of HX (negative for free HF to positive for HI) and will also vary with the locally excited region of the potential. This will condition the dynamics of

Figure 12. Action spectra recording the $\text{CaX}(\text{A}^2\Pi)$ emission while scanning the laser inducing the excited-state reaction; top $\text{X} = \text{Cl}$, bottom $\text{X} = \text{Br}$. The van der Waals precursor has been created in a supersonic beam resulting from the mixing of laser-ablated calcium in argon containing HX . One notes the great similarity of the spectra extending from $20\,000\text{ cm}^{-1}$ (500 nm) to $25\,000\text{ cm}^{-1}$ (400 nm) and the prominence of vibrational structure. The $4s^2\ ^1\text{S}_0\text{--}4s4p\ ^1\text{P}_1$ calcium line arising from collisions is indicated as a reference while the $4s^2\ ^1\text{S}_0\text{--}4s3d\ ^1\text{D}_2$ line is not observed but marked; therefore, the bands are labeled according to the locally induced transition P or D after the neighboring calcium line. Adapted from Ref. [243].

the excited-state reaction and its branching to excited-state products among which the Ca-HBr system is the most efficient.

To investigate excited-state potentials of these complexes, in the same manner as for Hg-Cl_2 , action spectra were recorded, detecting the $\text{A}^2\Pi$, $\text{B}^2\Sigma$ states of CaX . These spectra are remarkably similar in appearance from Ca-HF through Ca-HI . What is striking, in contrast to the former example Hg-Cl_2 , is the presence of extended structures corresponding to vibrational progressions in the spectra, as seen in Figure 12.

The spectra indicate that the excitation is local, corresponding to the promotion of a 4s calcium electron to a 4p or 3d orbital. This stems from the general appearance of the action spectra with two regions on the side of each atomic transition $\text{Ca}^1\text{P}_1 \leftarrow \text{Ca}^1\text{S}_0$ or $\text{Ca}^1\text{D}_2 \leftarrow \text{Ca}^1\text{S}_0$. The spectral distribution of these transitions is similar to the equivalent transitions of nonreacting van der Waals complexes with metal chromophores. The spectral distributions and the vibrational progressions have been interpreted with model potentials. This interpretation was confirmed by the calculations of Dubernet and Hutson on the open-shell van der Waals complexes Ca-HX correlating with Ca^1P_1 [248]. They found that the electrostatic interaction between the excited Ca (quadrupole) and HX (dipole) yields the following potentials, which are labeled according to the C_2 symmetry group:

- two states of A' symmetry, one with a linear equilibrium geometry similar to that expected for the ground state of the complex and another with an in-plane 4p calcium orbital. The two potentials exhibit an avoided crossing and states in separate energy domains result: the low-energy linear complex with $p\sigma$ configuration and a high-energy nonlinear complex with an in-plane 4p orbital.
- another of A'' symmetry with a T-shaped equilibrium geometry and an out-of-plane 4p orbital.

In the action spectra the states have been well identified. The first A' transition corresponds to the $4p\sigma$ linear complex observed in the red part of the spectrum with respect to atomic line (labeled P_a in Figure 12) and the A'' excited T-shaped follows with an extended vibrational progression (labeled P_b in Figure 12). On the blue side of P_b bands, the remaining transition A' can be found in the case of Ca–HCl at $24\,700\text{ cm}^{-1}$, as a broad, distinct, weak structure. From the ground-state geometry of the complex with a linear $\text{Ca} \cdots \text{HX}$ structure, the general features of the observed spectra are reproduced in the model of local excitation: similar red shifted to the $\text{Ca } ^1P_1$ line corresponding to the $A' \rightarrow A'$ absorption within the complex and blue shifted absorption with intense bending transitions corresponding to a 90° geometry change in the $A' \rightarrow A''$ transition.

The same line of argument can be invoked for the 1D domain in terms of the local excitation of the calcium. The observation of two domains, D_a and D_b , is clear for all the complexes except for Ca–HF, where only the blue-shifted domain D_b is apparent in the action spectra. The observation of the atomic forbidden transition $4s3d\ ^1D_2 \rightarrow 4s^2\ ^1S_0$ within the complex has been interpreted for HCl, HBr and HI [249, 245] as a lifting of the S–D forbiddenness in the complex through mixing with the nearby 1P_1 states of A' and A'' symmetry.

As an example, the dynamics of the reacting complexes in the A'' state (T-shaped complex with the $4p\pi$ orbital out of the plane) are well described by wavepacket calculations. The experimental result is shown in the left panel of Figure 13 (top curve), where only the group of bands located on the blue side of the calcium line, which were labeled P_b in Figure 12 are relevant to the A'' excitation. A two-dimensional potential has been used for the Ca–HBr complex to model the evolution of the hydrogen motion for a fixed Ca–Br distance. The surface is constructed from the bending Ca–HBr van der Waals potential [244] and the Morse potential representing HBr. The reaction on the surface corresponds to the H atom passing the transition state, which is a narrow channel at a 120° bent configuration of the Ca–H–Br molecule (see the upper right panel of Figure 13. The reactive trajectories initiated from the Franck–Condon region represented at 0° in the same panel can find this channel either directly or after one or several oscillations. Quantal calculations of the reactive flux are made numerically by wavepacket propagation [241, 242]. This is the quantal analog of classical trajectories. The probability of returning close to the origin is given by the autocorrelation function shown in the bottom right panel of Figure 13. The Fourier transform of this function simulates the action spectrum of the reaction. The result of this simulation is shown as the bottom curve in the left panel of Figure 13. The potential surface shown and more specifically the position and width of the funnel were adjusted for the simulation to reproduce the

Figure 13. Result of the two-dimensional calculation for Ca-HBr. The calculation and the spectrum of the $P_b(A' \leftarrow A'')$ transition are compared on the left. The two-dimensional surface built on the reaction coordinate R_{H-X} and the Ca-HX bending angle is displayed in the top-right panel. The propagation was performed over 1.25 ps. Each contour corresponds to 500 cm^{-1} . The contour of the Gaussian wavepacket issued from the ground state by vertical excitation is also shown in this surface. The bottom panel on the right shows the resulting modulus of the autocorrelation function with clear recurrences. Adapted from Ref. [243].

positions and width of the experimental action spectrum [243]. It must be mentioned that the fit is not very sensitive to the bending angle, but the essential conclusion is that the transition state is far from linear.

The picture of the reaction is that of the Ca-HBr complex having bending oscillations on either side of the channel where it reacts with high efficiency. Outside this geometry no reaction occurs. This is a one-potential picture whereas two potential surfaces are expected in harpoon reactions: a covalent and an ion-pair surface. This is due to the locally high efficiency of the coupling between both surfaces at the bent configuration of Ca-H-Br. Presumably, this can be due, at least partly, to an optimum overlap between the diffuse antibonding orbital (LUMO) of HBr, mainly localized on the hydrogen, and the 4s orbital of calcium at nonlinear geometries of the Ca-HBr complex. In the same manner, the action spectrum for the reaction in the Ca \cdots HI complex is broad and almost featureless, corresponding to an even broader intersection between the ion-pair and covalent surfaces.

In contrast, this single-surface model does not apply to Ca-HCl, and a two-surface calculation was performed where the H-atom departure is induced by the electron jump from the van der Waals potential to the electron transfer potential. The quantal nature of this nonadiabatic transition allows one to reproduce all the features of the spectrum. This includes the small linewidth of some transitions and, more important, the inverse energy dependence observed in the spectrum, where the broadest bands are those of lowest energy [244], in figure 13.

Lastly, the action spectra in Ca–HF close to the energy threshold to chemiluminescence display very narrow lines, indicating the partial closure of the corresponding reactive excited-state channel. This indicates that the observed channel luminescence is independent of the ground-state channel that could also contribute to the broadening of the lines in the spectrum and confirms the model of the 4s electron hop separated from the 3d hop. We shall now examine the effect of this hop on the efficiency of production of excited states.

Mechanism of production of excited states: excited ionic curves

The mechanism for the production of excited states has already been invoked in the case of excited-state barium reactions. It was also discussed by Rettner and Zare when investigating polarization effects in the chemiluminescent reaction of aligned $\text{Ca}(4s4p\ ^1P_1) + \text{HCl}$ and other halogenated molecules [224, 225]. Following their analysis, the excited states of the calcium product correlate directly with an excited ionic electron-transfer potential; here the lowest is the $\text{Ca}(3d\ ^2D)^+ + \text{HX}^-$ potential. The reaction results from the crossing of the locally excited potential correlating with $\text{Ca}^* + \text{HX}$, with this excited ionic potential $\text{Ca}(3d\ ^2D)^+ + \text{HX}^-$. Specifically, it is shown that the crossing is possible within the range 3–5 Å of the excited van der Waals potential [245]. There result symmetry effects, termed core symmetry conservation, where the excitation of a specific excited state of the complex (of a given orbital symmetry) yields CaX products in the equivalent symmetry. A'' and A' states of the Ca–HX complex yield preferentially states of CaX with Π or Σ symmetries, respectively. This corresponds to the covalent–ion-pair crossing where the 4s electron of the calcium has transferred to HX leaving the Ca core with the initial symmetry. In Figure 14 an example is given of this preferred core conservation where the A'' symmetry excited Ca–HBr complexes form preferentially the CaBr $A^2\Pi$ state and conversely A' states of the complex will populate the CaBr $B^2\Sigma$ state, despite the unfavorable energetics: the lowest energy state of the product should always be the most populated. The flux to the CaBr $A^2\Pi$ state, although being modulated by the excitation in either the P_a (A') or P_b (A'') transitions, is always important. The reason for the lesser correlation of the A' excited state of the $\text{Ca}\cdots\text{HBr}$ complex with $\text{CaBr}(B^2\Sigma^+)$ emission, may be found in the outer electron transfer, at the crossing of the ground-state ionic curve and the locally excited state. Reactive trajectories passing through this crossing are not expected to yield chemiluminescence, but ground-state CaBr instead. Here, in A' symmetry with the Ca 4p orbital pointing towards HCl in σ symmetry, the electron transfer will trap states of core Σ symmetry and divert them from chemiluminescence. The flux to $B\Sigma$ states will be decreased accordingly.

As outlined above, the mechanism for channeling reactive flux into the chemiluminescent channels via the inner crossing with the excited ionic potential accounts well for the effect of the preferential population of $\text{CaCl}(A^2\Pi)$ observed in the full collision experiment $\text{Ca}4s4p\pi + \text{HCl}$ performed by Rettner and Zare [225]. It is supported further by elegant experiments performed by Gonzalez Ureña's group on full collisions of $4s3d\ ^1D_2$ metastable calcium atoms with HX molecules ($X = \text{Cl}, \text{Br}$) at variable translational energies. The production of chemiluminescent

Figure 14. Chemiluminescence spectra of CaBr following different excitations of the $\text{Ca} \cdots \text{HBr}$ complex, as indicated by arrows connecting the excitation region on the action spectrum (displayed vertically at the left of the figure) to the corresponding chemiluminescence spectrum (shown horizontally). From top to bottom P_b , P_a the ratios, from simulations, are $(\text{A/B})_{\text{P}_b} = 2$ and $(\text{A/B})_{\text{P}_a} = 1.1$, respectively. Next come D_b and D_a whose ratios are 11 and 5, respectively. Adapted from Ref. [245].

species CaX in the $\text{A}^2\Pi$ or $\text{B}^2\Sigma$ states shows a clear threshold at 280 meV for HCl [250] and 215 meV for HBr [251]. This threshold was modeled as a barrier due to the crossing with the excited ionic potential correlating with the excited ion $\text{Ca}(3\text{d},^2\text{D})^+$ [252]. This crossing labeled 2 in Figure 15 results in 4s electron transfer to HX, thus forming an excited ionic complex. In order to access this inner crossing the system has to pass the crossing labeled 1 that mixes the $\text{Ca}(4\text{s}3\text{d } ^1\text{D}_2) + \text{HX}$ and $\text{Ca}(4\text{s}4\text{p } ^1\text{P}_1) + \text{HX}$ covalent potentials. The coupling is, as we have seen, important and therefore the process is efficient. This mechanism proposed by Rettner and Zare [225] finds quantitative confirmation here. In turn, the formation of the ground-state products proceeds directly at the outer crossing 3 with the ground-state ion curve by Ca 4p electron transfer to HX.

Quasi-direct excitation of the electron-transfer potential surface in the Ca–HCl complex

The other important channel in the decay of the Ca-HX complex, ground state of the product CaCl , can be observed by laser-induced fluorescence and a very high vibrational excitation is detected. This high vibrational excitation arises from the sudden release at 4 Å of the ground-state CaCl molecule, and thereby in a highly excited vibrational state, the distribution, maximum at $v = 30$, extends to $v = 60$. The resultant energy distribution has been interpreted with the use of the DIPR-DIP model [246].

Figure 15. Schematic diagrams of the one-dimensional interaction potentials between Ca and HX in the vicinity of the 1P_1 and 1D_2 states of calcium. The crossings with the ground-state 2S and 2D electron transfer potentials are indicated by the numbers 1, 2 and 3. Also represented is the most favorable electronic configuration of the calcium for this transition. Adapted from Ref. [252].

The action spectra when monitoring the high vibrational levels of the ground state of CaCl appear strikingly different from the preceding structured spectra when detecting the chemiluminescence. In the case of excited product detection, the action spectra are assigned to local electronic excitation of the calcium within the Ca–HCl complex, resulting in states of A' or A'' electronic symmetry correlating with the optically accessible calcium states $4s4p\ ^1P$ or $4s3d\ ^1D$, within the complex. On the other hand, the continuous action spectrum exhibiting a Gaussian shape when detecting ground-state CaCl is assigned here to an excitation of a different nature, i.e., the direct excitation of the charge-transfer surface Ca^+HCl^- with A' symmetry correlating with the $\text{Ca}^+\ ^2S_0$ ground-state ion. The excitation region corresponds to a fairly steep potential surface, the lowest charge-transfer potential surface $\text{Ca}^+(4s\ ^2S) - \text{HCl}^-$, that correlates with the ground-state products $\text{CaCl}(X) + \text{H}$. Vertical excitation of this surface from the ground state of the Ca–HCl complex is possible owing to its partial ionic character [253]. The transition intensity can be represented by excitation to a Coulomb potential along the coordinate $R_{\text{Ca-HCl}}$, with the equilibrium distance of the ground-state complex as 3.8 Å and the width of the potential as 0.5 Å. With this simulation there is reasonable agreement, given the simplicity of the model.

Absorption of the Ca–HCl complex at different frequencies can be linked with different regions of the potential energy surface and the resulting branching to the different product states is noticeably different. The yield of chemiluminescent products is only important for excitation of certain regions of the potential surface that cross at reasonable distance from the equilibrium with a potential surface correlating with an excited ion core $\text{Ca}^+ \text{ } ^2\text{D}$. Also, it can be expected that the decay of the initially excited state in the case of the local excitation of the calcium and in the latter case of the direct excitation of the charge-transfer potential have different appearances.

The latter excitation of the ionic region in the red of the action spectrum will result in immediate Cl abstraction to form CaCl while the local A'' excitation in the same spectral region will necessitate a reasonable rearrangement before the excited CaCl^* product is formed. Time-resolved experiments have been conducted on the Ca–HBr system within the $\text{Ca}(4s4p \text{ } ^1\text{P}_1)$ region and a 200 fs decay time of the initially excited complex has been observed [254]. This confirms the local nature of the excited state of the calcium. The 200 fs decay might correspond to the time necessary to reach the transition state from the Franck–Condon region.

Ground-state products from locally excited reactions in alkali metals

The detection of nonfluorescent ground states within a large population distribution is a difficult problem, as we have just seen for Ca–HCl. A new and general method has been proposed by John Polanyi's group to address this problem in clusters. Here also the reacting system composed of a metal and a molecule or an aggregate of molecules is prepared in a locally excited state of the metal, yielding short-lived quasi-bound states whose resonances are analyzed to unravel the electron-transfer reaction.

The equivalent of an absorption spectrum of the short-lived reaction complex can be measured by depletion spectroscopy. The absorption spectrum of the reacting intermediate is monitored via the decrease in the ground-state population of the ground-state van der Waals complex of the reagents, due to the reaction from the excited state. This is achieved by the use of two lasers, one probing, by ionization, the population of the ground-state complex formed by the reagents and the other, intense, exploring the reacting excited surfaces, thus causing a decrease in this population by funneling population into the reaction channel. The major advantage of this method compared with laser-induced fluorescence, used in the preceding section, is that it is sensitive to electron-transfer reactions of nonchemiluminescent or nonluminescent products. This occurs especially in the case of polyatomic molecules such as fluorobenzene and methyl fluoride with sodium [255, 256]. However, the method yields the detection of the sum of all nonradiative decay channels of the excited state, fluorescent or nonfluorescent. It has the advantage of giving the absolute excitation cross-section, by measuring the dependence of the ion signal on the intensity of the depletion laser. The absorption cross-section can be directly derived from the relative disappearance of the ion signal as

$$\log\left(\frac{N_0}{N}\right) = \sigma_{\text{depletion}} F \quad (24)$$

where F is the laser fluence of the depletion loss expressed in photons per unit area [257]. This cross-section is directly related to the absorption and decay process:

$$\sigma_{\text{dep}} = \frac{4\pi^2\omega}{c} |\mu_{if}|^2 \frac{\Gamma_f}{(E - E_f)^2 + \Gamma_f^2} \quad (25)$$

where μ_{if} is the $i \rightarrow f$ transition dipole moment and Γ_f represents the linewidth derived from the golden rule expression. This formulation of σ_{dep} is similar to the intensity in the absorption spectra derived in the case of $\text{Hg}-\text{Cl}_2$ where it is assumed that all the excited molecules have reacted ($\Gamma_f \gg$ determining).

Moreover, using high laser fluences one can saturate the $i \rightarrow f$ transition in a manner that depends on the excited-state lifetime. Measuring the energy saturation threshold will relate directly to the decay time of this accessed reactive excited state: a long decay will correspond to a low saturation threshold, and the converse.

Various systems have been investigated: $\text{Na}_2 \cdots \text{ClCH}_3$, $\text{Na}_2 \cdots (\text{ClCH}_3)_2$, $\text{Na} \cdots \text{FPh}$ [255], $\text{Na} \cdots (\text{FCH}_3)_n$ ($n = 1-4$) [256]. The photoinduced charge-transfer dissociation spectra observed for these systems all reveal the local nature of the excitation. In the case of $\text{Na} \cdots (\text{FCH}_3)_n$ ($n = 1-4$), for each value of n three broad peaks appear on the red and blue sides of the sodium D line. As before, the interaction of $\text{Na}(3^2\text{P}_J)$ with CH_3F results in the formation of these electronic excited states $|\Lambda = 1/2, \Omega = 1/2\rangle$, $|\Lambda = 3/2, \Omega = 1/2\rangle$, $|\Lambda = 3/2, \Omega = 3/2\rangle$. Vibrational structure is most prominent for the largest complexes with a spacing of 270 cm^{-1} , a standard value for strongly bound van der Waals clusters.

A relatively large cross-section (1.2 \AA^2) was obtained for the photoreaction of the excited state of the $\text{Na} \cdots (\text{FCH}_3)$ complex, this seems indicative of a very favorable geometry to reaction. It compares with a negligible cross-section for reaction in collisions within crossed beams [164]. The reasonably high value of the cross-section implies also that the electron transfer can proceed without a barrier. If the electron affinity of the CH_3F molecule were that of the free molecule, there would be a very high barrier at ca. 6 eV. This suggests that the $\text{F}-\text{CH}_3$ bond is substantially released at the transition state to accommodate the electron and allow a crossing of the ionic potential $\text{Na}^+ \cdots (\text{FCH}_3)^-$ van der Waals potential at the distance $R_{\text{Na} \cdots \text{FCH}_3} \approx 3 \text{ \AA}$, close to the Franck-Condon excitation region accessed from the ground-state complex. The increase in the electron affinity in stretching the $\text{F}-\text{CH}_3$ bond can be understood, since at infinite distance the electron affinity must reach +3.45 eV (atomic fluorine), starting from -6.2 eV in the molecule. The different intensities of the different peaks in the depletion spectrum were inferred from the different perturbations of the sodium by the complexing FCH_3 molecule. The peak cross-section also decreased with the size of the complex in a way that may reflect the formation of an inner solvation shell closed at $n = 3$. This system represents the first one where gradual solvation effects have been observed on an electron-transfer reaction.

The prototypical $\text{Na} \cdots \text{HF}$ system has been investigated by the same method. It represents an excellent example where elaborate and accurate calculations (MRDCI)[75] are possible for the ground and excited states of the complex. Also,

Figure 16. (a) Experimental photodepletion spectrum of the Na...FH complex and (b) calculated absorption spectrum assuming $T = 250$ K. Adapted from Ref. [75].

the reaction is best activated by electronic excitation since it is endoergic by ca. 1.3 eV. The depopulation spectrum represented in Figure 16 displays two bands, a small one at 780 nm and a strong one at 650 nm in the immediate red region of the sodium D line. In contrast to the preceding case of Na...FCH₃^{*}, the number of bands is only two in the depopulation spectrum instead of three and the spectrum extends also over a considerable range. There is an extensive vibrational structure within these bands. The calculations reproduce with great accuracy the position of the bands, their shape and the detailed vibrational structure. These bands have in essence the same origin as in the case of Na...CH₃F and result from the interaction of excited Na(3p²P) with HF, which is very strong in this case and explains the extent of the spectrum over 1 eV. It is interesting to note the geometries of the three states, the lowest energy state $\tilde{A}(2A')$ of quasi-diatomic symmetry Σ , correlating with Na(3p²P_{1/2}), is bound by 0.53 eV and bent at 60°; in contrast, the next two degenerate states, B(3A', 1A''), correlating with Na(3p²P_{3/2}), are linear and bound by 0.34 eV. The geometry changes between the ground state (0.076 eV) and the excited states account for the extensive vibrational structure both in the Na–FH stretch and bends.

The dynamics of the photoreactive intermediate are complex and still need to be elaborated in detail. There is a strong avoided crossing, the locus of the electron transfer between the exciplex $\tilde{A}(2A')$ state and the ground X state where the reaction occurs. Dynamic calculations show [258] that the system is trapped in the excited $\tilde{A}(2A')$ exciplex before undergoing a nonadiabatic relaxation to the ground state and that this relaxation is quantal owing to the large energy gap between the two states. The calculations also show the very long lifetime of the excited state (several hundred picoseconds) which can be dramatically decreased by the H/D

isotope effect and excitation of the HF vibration. There is a complex process where conical intersections come into play to funnel the system from the B to the \tilde{A} state and the avoided crossing further funnels the excited-state reagents to the ground state. The reactive process can no longer be understood as a classical process leading through a crossing between the electron-transfer potential and the initial covalent potential to the reaction products involving a nonadiabatic process. This also showed up in the preceding section in modeling the sharp resonances observed in the Ca–HF reacting complex [246].

2.6.2 Time-resolved Observation of Electron Transfer in Excited-state Reactions: the Ba–FCH₃ case

The spectrum of the Ba–FCH₃ complex has also been probed via photodepletion spectroscopy and it displays strong transitions in the region of the Ba 1P_1 line with a 60 Å² cross-section [259, 260]. This corresponds to the local excitation observed in the preceding section which results in the corresponding splitting (here doubling) of the p transitions.

The dynamics of the system have been explored by femtosecond pump–probe techniques [261] through the excitation of the intense band observed at 618 nm. This band, although being slightly asymmetric, can be assigned a homogeneous linewidth of 220 fs from the uncertainty principle. The decay of the parent (270 fs) was found to match exactly the appearance time of the fragment BaF with no delay and populated in an excited C electronic state quasi-exclusively. The lack of delay between the disappearance of the parent and the appearance of the product BaF* is surprising in a scheme where the locally excited parent complex should undergo an evolution on the reaction surface bringing it from the Franck–Condon accessed region to the transition state and the products. What can be concluded, however, is a rapid, direct passage over the electron-transfer transition state Ba⁺–FCH₃[–] involving a nonmeasurable delay between the excited state of the reagents and the products; this must correspond to the absence of a barrier separating them.

2.6.3 Direct Excitation of an Electron-transfer Complex

Direct excitation of electron-transfer states may yield surprising results. This is the case with the bimolecular benzene–iodine charge-transfer complex. In solutions this system is the prototypical case of charge transfer as reported by Mulliken [262]. The characteristic 280 nm absorption band of the benzene–iodine system is distinct from any absorption features of neat iodine or benzene. It has been identified as being due to a promotion of the HOMO benzene π electron to a σ^* LUMO orbital on iodine resulting in benzene–iodine electron transfer.

Hence, in a benzene–iodine cluster, excitation at 266 nm leads to the charge-transfer potential energy surface. Using femtosecond excitation one can detect the decay of the initially populated state, the appearance of the products and their kinetic energy distribution and alignment (with respect to the pump laser) [55, 56,

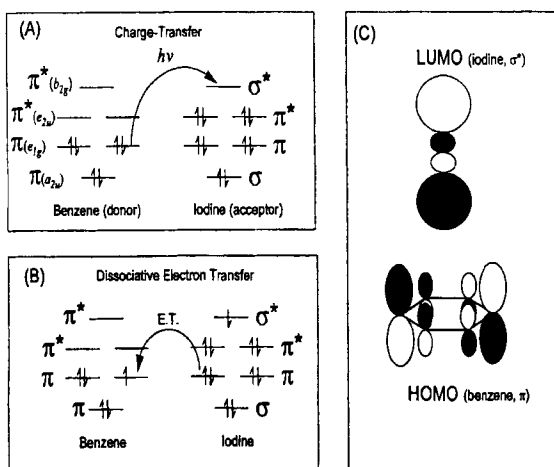

Figure 17. (A) schematic diagram showing the electronic configurations of benzene and molecular iodine. The arrow represents the electron transfer excitation from the HOMO of the donor to the LUMO of the acceptor, iodine. (B) Schematic diagram of the back electron transfer process which leaves the molecular iodine electronically excited. (C) Pictorial representation of the HOMO in benzene and the LUMO of iodine. Adapted from Ref. [55].

263, 264]. The decay of the parent is biexponential with a short time constant, typically 250 fs, and a longer one, 800 fs. The kinetics appear to be parallel, i.e., correspond to different and competing decay channels. Their pre-exponential factors are different, with the short one dominating. The short decay has been assigned to an ionic to covalent back electron transfer pictured in Figure 17, resulting in iodine dissociation. A back transfer from the iodine π^* orbital to the half-filled benzene π orbital leaves iodine in a dissociative state. The reaction channel forms $(\text{benzene})^+ \text{I}^- + \text{I}$, and corresponds to the minor decay component of the parent.

The neutral decay channels have been shown to outnumber the ionic channels and are carefully analyzed by determining the energy distribution (kinetic) of the released iodine atom and its recoil direction via polarization measurements. A double energy distribution has been found with a low-energy component and another one located at $+4000 \text{ cm}^{-1}$. The latter high-velocity iodine recoils directly away from the benzene ring in a very short time (700 fs) while the slower velocity component is detected and presumably corresponds to the other iodine atom lying closer to the benzene ring as shown in Figure 17. The geometry of the cluster corresponds to an iodine molecule slightly tilted away (30°) from the C_6 axis of the benzene molecule and during the dissociation one of the atoms rebounds on the plane of benzene with lesser energy and appears after a longer time. This is confirmed by polarization measurements and appears also in molecular dynamics simulations. A very interesting feature of this work is to analyze the results of iodine caged in large benzene, or benzenic, clusters; there the escaping iodine atom appears with a considerable delay (up to 75 ps), as might be expected, and with lesser energy. This type of experiment has been compared with liquid-phase results [265] and a major difference is the observation of a benzene $\cdots \text{I}$ cage complex resulting from the I_2 dissociation.

This charge-reverse electron-transfer process has been studied systematically with a variety of electron donors and iodine and ICl as acceptors in the precursor. The

general phenomena of reversible and dissociative electron back transfer are observed for all systems studied. However, in the case of diethyl sulfide and iodine complexes [56] trapping can occur at the transition-state level where the reversible electron transfer can be delayed by 500 fs followed by the release of the first iodine atom. One notes that this mechanism of bond breaking due to the reverse transfer of the electron is symmetric with that developed in the harpoon model where the negative ion resulting from the direct transfer is dissociated.

2.7 Prereactive Behavior in Ground States

Within the framework of the harpoon reactions described at the beginning of this chapter, ground-state reactions occur between an electron donor and an electron acceptor, because an electron is totally transferred from the donor to the acceptor. Of course, situations must exist where an electron is transferred but the reaction does not occur owing to energetics. Thus the charge-transfer complex can be stabilized before reaction. Other situations can be encountered where the electron transfer is only partial. These situations can be named prereactive to highlight the fact that the reaction is blocked somewhere along the reaction path.

2.7.1 Stabilizing an Electron-transfer Complex

Prereactive behaviors were identified very early and an impressive series of examples was listed in a book by Klabunde in 1980 [266]. Electron spin resonance (ESR) studies reveal that in low-temperature matrices electron-transfer reactions are blocked as a rule and most, if not all, charge-transfer complexes involved in standard gas-phase harpoon reactions have been stabilized and observed in matrices. The ESR spectra of these systems revealed nearly complete electron transfer. Similar conclusions have also been drawn from infrared spectroscopy. For example, outside the field of alkali metal atoms, evidence of an Al^+NO^- complex has been obtained by this technique [267]. It should not be thought that every metal atom is able to make charge transfer with every molecule. For example, no indication exists of a charge transfer between Cu and NO in an argon matrix [268].

Let us consider an illuminating example concerning an alkali metal atom: the harpoon reaction

which was extensively studied in the gas phase by Brooks and co-workers [123, 124]. The K–HCl system has also been studied in an argon matrix [220]. The ESR spectrum in the matrix study, which is normally very sensitive to the presence of atomic hydrogen, indicates only a very little tendency to form $\text{KCl} + \text{H}$ compared with a very easy formation and stabilization of the electron-transfer $\text{K}^+ \cdots \text{HCl}^-$ complex.

Of course, this suggests a barrier on the potential energy surface, which prevents further reaction of the complex to form $\text{KCl} + \text{H}$. With the classification of Polanyi such a barrier is a *late barrier*, localized somewhere in the exit channel of the reaction [70, 73]. With such a barrier, translational energy is less efficient at promoting the reaction than a comparable increase in the vibrational energy of the HCl reaction partner [269]. This anticipation based on the ‘Polanyi rule’ for barrier location was exactly confirmed by the gas-phase measurements of Brooks and co-workers [123, 124].

2.7.2 Observing Partial Electron Transfers in the Gas Phase

When facing a full collision process, the existence of such a partial electron transfer state is elusive and usually difficult to evidence experimentally. A major difficulty comes from its transient character. A convenient approach to stabilize the electron transfer between two encounters is to consider a complex formed with both of them. This was the case with the $\text{Au}^+(\text{H}_2\text{O})$ complex mentioned above. This is also the case with the neutral van der Waals complexes considered hereafter. In this case, the characterization of the charge-transfer state requires a careful experimental investigation. We review here how spectroscopy of these clusters can characterize partial electron transfers.

This is probably the most delicate and quantitative way of characterizing partial charge transfer in binary pairs. These pairs are stabilized for an ‘infinite’ time within a molecular complex where the charge-transfer properties can be examined. Two methods have been used: Stark spectroscopy and pulsed Fourier transform rotational spectroscopy. The first method diagnoses the dipole moment of the molecular complex under study, and hence the distribution of charges. If the dipole moment has increased within the complex due to charge transfer, a positive signal is observed. This direct method has been mainly applied to cooled gas mixtures containing a small fraction of dimers. This method could be enhanced by the development of Stark spectroscopy in supersonic molecular beams [271]. A systematic study of the charge-transfer properties in various complexes of electron donors with electron acceptors, has been performed by Legon [270, 272] by rotational spectroscopy (pulsed Fourier transform). The electron transfer is monitored here via the hyperfine splitting observed in these spectra.

In an atom, the nuclear quadrupole having unpaired electrons interacts with the field gradient in its vicinity. This provides an accurate measurement of the charge distribution around this atom. The hyperfine splitting, precisely measured with microwave accuracy, yields the hyperfine coupling constant $\chi = eqQ$, where e is the proton charge, Q is the nuclear quadrupole and q is a quantity depending on the charge distribution around the nucleus. In this case, q relates to the average field gradient $\langle \partial^2 V / \partial r^2 \rangle_{\text{ave}}$ about the atom and is given by the following expression:

$$q = e \int \Psi_{JJ}^* \frac{3 \cos^2 \theta - 1}{r^3} \Psi_{JJ}^* d\tau \quad (28)$$

where J relates to a state of total electronic angular momentum J and $mJ = J$. In a method originally developed by Townes and Dailey [273], q is now measured in molecules but the atom is bound within a chemical bond. However, on average one unpaired electron remains about this atom and the wavefunction can be expanded as a linear combination of atomic orbitals. In the case of an atom Cl, for example, accepts a second charge becoming Cl^- , and becomes spherically symmetric and $q = 0$. It is then found that, in the case where the molecule is partially ionic, the wavefunction is a superposition of neutral and ionic contributions with probabilities $1 - x$ and x , respectively. Hence q becomes a linear combination of the neutral and ionic contributions: $q_{\text{neutral}}(1 - \delta) + \delta q_{\text{neutral}} (= 0) = q_{\text{neutral}}(1 - \delta)$. This has been successfully applied to molecules of increasing electronegativity [273]. Of course, the q value of ^{35}Cl in NaCl , i.e., Na^+Cl^- , is zero.

In a cluster formed by a donor molecule D with an acceptor A, partial charge transfer may occur between these units, but the derivation of q from quadrupole splitting measurements of one atom requires a detailed analysis. Considering the acceptor subunit ClBr , for example:

- $\chi(\text{Br})$ is increased while $\chi(\text{Cl})$ is decreased by the charge distribution of the nearby donor;
- the $\chi(\text{X})$ values will be decreased by angle averaging the large amplitude oscillations of ClBr about the axis of the complex, $\chi(\text{Cl}) = \chi(\text{Cl})_0(3 \cos^2 \beta - 1)$ [274].

The results are conclusive since in clusters with Cl_2 and BrCl as acceptors with a manifold of donors, a direct relationship of the amount of charge transfer δ with the force constant of the intermolecular mode $\text{D} \cdots \text{A}$ was found, as seen in Figure 18. This increased force constant results from the interaction between the induced

Figure 18. Partial electron transfer $\delta(\text{B} \cdots \text{XY})$ versus the van der Waals bond force constants. Adapted from Ref. [270].

charges in the cluster. From these measurements it appears that the amount of charge transfer is much smaller than expected, even for well known systems such as $\text{NH}_3 \cdots \text{HCl}$, that could be believed to be ionic. In Figure 18 very small amounts of charge transfer δ are observed for an ensemble of donors and acceptors, which shows the power of the approach and also correlates the strength of the bond with the partial charge transfer δ .

2.8 Towards Electron-transfer Reactions in Condensed Phases

Few experiments allow one to bridge gas-phase electron transfer mechanism to liquid (or condensed)-phase electron transfer reactions. The major problem is to model the so-called solvent coordinates in the gas phase. Of course, clusters seems to be the ideal medium to build solvent effects in a stepwise manner. However, clusters are much colder than liquids, with the consequence that only a limited number of isomers are explored, as compared with the room temperature configurations involved in liquid processes. Discrepancies are observed in the case of cluster solvation of ionic molecules in clusters: NaI remains at the surface of water clusters whereas it dissolves in bulk water [275]. Clusters thus do not allow one to explore in a single step all the aspects of a liquid-phase electron-transfer reaction. Their main advantage arises from this limitation since they allow one to study separate aspects of the solution processes.

Hence there is no gas-phase experiment yet which fully encompasses all aspects of an electron-transfer reaction in solution. In solution, the solvent acts first as a polarization medium, which affects the energetics of direct transfers from the donor to the acceptor. It can also act as a transport medium for indirect electron transfers. The first aspect has been addressed in various cluster experiments [276]. The second aspect was addressed more recently by considering the femtosecond dynamics of iodide-(water) $_n$ anion clusters, as reviewed below [277]. Finally, clusters present the advantage of isolating one reaction pair free from secondary collisions, except those, which are desired, with the solvent molecules (or atoms). The latter consideration motivated the cluster isolated chemical reaction (CICR) technique reviewed in Section 2.8.3.

2.8.1 Solvent-induced Electron Transfer in Clusters

Metals with low ionization potentials such as the alkali metals (lithium through cesium) dissolve in polar solvents such as ammonia and the electron of the metal is solvated in a small cage surrounded by the polar molecules, while the corresponding metal ion is strongly stabilized by the solvent dipoles. This represents an example of solvation effects inducing charge separation and the process can be essential in stabilizing reaction intermediates resulting from electron transfer.

The effect of the medium inducing this electron transfer can be modeled experimentally in the corresponding metal-molecule clusters where the gradual onset of

electron transfer is monitored by measuring their ionization potentials. Excellent experiments by Schulz et al. [278] and Haberland and co-workers [279] have achieved that goal: the ionization potential of sodium–ammonia clusters decreases in size and suitable extrapolation of the ionization potential yields the value of 1.45 eV for the infinite size cluster. On the other hand, the photodetachment of the electron attached to a cluster of ammonia of infinite size is also 1.45 eV, as shown by Haberland and co-workers [279]. Thus in sodium clusters within ammonia, the lone electron from the sodium atom becomes increasingly delocalized within the cluster as its size increases finally to form a volume/surface solvated electron whose detachment energy from both experiments is 1.45 eV. The same experiments performed with other alkali metal atoms [280] reach the same detachment value, indicating that it is a property of the solvated electron and not of the metal. Also similar experiments have been made on the equivalent water clusters and the ionization potential of the clusters quickly reach the limiting value of 3.3 eV for clusters containing five water molecules. This demonstrates the efficiency of a limited number of polar molecules to stabilize the charged intermediates resulting from the electron transfer.

2.8.2 Dynamics of Electron Solvation in Finite Water Clusters

Solvent-mediated electron-transfer reactions involves the transient transfer of an electron to the solvent acting as a bridge between the donor and the acceptor [1]. Clusters offer the possibility to split this sequential process, the first step of which is the transfer of an electron from the donor to the solvent. In the absence of an acceptor, this step also occurs in solution, but cluster experiments allow a more direct characterization as follows.

Electron solvation dynamics in photoexcited anion clusters of $\text{I}^-(\text{D}_2\text{O})_{4-6}$ and $\text{I}^-(\text{H}_2\text{O})_{4-6}$ have been studied by Neumark's group at Berkeley, using femtosecond photoelectron spectroscopy. The experiment follows the pump–probe scheme, where the pump prepares the cluster analog of charge transfer to solvent by transferring the electron of I^- to the attached water moiety of the cluster. The system is probed by photodetaching the excess electron. Evidence is given of electron solvation dynamics of the excess electron by rearrangement of the solvent molecules for cluster sizes $n = 5$ and 6. This arises from an isomerization from an initially formed dipole bound state (very diffuse electron outside the water cluster) to a conformer where the excess electron is more localized (solvated). This step lasts ca. 1 ps, as shown by the shift of the photoelectron detachment energy to lower values. It corresponds to an important rearrangement of the solvent, prefiguring what should become a cage formed by water molecules.

2.8.3 Cluster Isolated Chemical Reactions

The cluster isolated chemical reaction (CICR) technique was developed in Saclay to permit quantitative studies of heterogeneous chemical processes at a microscopic level. The ultimate goal is to document the coupling between a reaction coordinate

and the degrees of freedom of a reaction medium. An ideal experiment in this direction would consist in isolating a single pair of reactants in a controlled environment, i.e., in a medium of known size, structure, internal energy, and interaction with the solute, and to observe its dynamics. The (CICR) technique is a way to approach such control. It consists in depositing reactants on free nanometric van der Waals clusters, that play the role of a reaction medium. A full account of the method is given in Ref. [281].

This section gives some details on the CICR method, then reviews results concerning the electron-transfer reactions of barium atoms and small barium aggregates with oxidizing molecules such as Cl_2 , CO_2 and SF_6 on argon clusters. More extensive descriptions of our work can be found in Refs. [281–287]. The CICR technique is now beginning to be developed outside our group; for example, it has been used to investigate the $\text{Ba} + \text{N}_2\text{O}$ reaction in helium clusters [288] and a charge-transfer reaction forming the Kr^+F^- excimer after excitation of the $\text{Kr}_n(\text{NF}_3)_m$ clusters with synchrotron radiation [289, 290].

Brief survey of the CICR technique

The CICR method is based on two important features, which are actually not independent of each other.

The first is the choice of fairly large, finite-sized van der Waals clusters for the environment of the chemical reaction (10^2 – 10^3 atoms or molecules in our case). At such sizes, the number of surface atoms is relatively important compared with the number of atoms staying inside the cluster, and in our case the reactants deposited on the clusters stay at the surface, but are free to migrate, to collide with each other and eventually to react.

The second important point on which the CICR technique is based is the strict control of the average number $\langle m \rangle$ of reactants deposited on the clusters. This is achieved by using the pick-up technique originally developed by Scoles and co-workers [291]. It consists in capturing the reactants by sticky collisions between the clusters and a low-pressure gas. Of course, the number of particles trapped is not the same for every cluster, but the important point is that the capture process has known statistics, being a random Poisson process. Hence the probability distribution $P_q(\langle m \rangle)$ of finding exactly q reactant molecule per cluster follows the Poisson law of order q :

$$P_q(\langle m \rangle) = \frac{\langle m \rangle^q}{q!} \exp(-\langle m \rangle) \quad (29)$$

The principle of the experiment is to record the reaction signal (e.g., a chemiluminescence signal) as a function of the average number $\langle m \rangle$ and to fit it by a Poisson distribution or by a linear combination of Poisson distributions. The order of the Poisson distribution which best fits the experimental data is a direct measure of the exact number of reactants involved in the chemical process under study, since the reactants are confined on a cluster of finite size. For instance, if the reaction signal is well fitted by the Poisson distribution $P_2(\langle m \rangle)$, when varying the average

Figure 19. Scheme of the experimental set-up.

number $\langle m \rangle$ of the reactant 'r' deposited per cluster, then we know that the reaction signal originates from the reaction of two reactants 'r', and only two. Since the binding energy between the two is usually much larger than the cluster temperature, these two reactants group together as a dimer. For instance, the binding energy of Ba_2 has recently been calculated to be 0.2 eV [292], a value that is much larger than the thermal energy available on clusters. This is the approach we used to investigate the reactivity of small barium aggregates Ba_2 , Ba_3 , etc. [283, 285, 293].

The apparatus used in CICR experiments is shown schematically in Figure 19 [285, 287]. The beam source (chamber 1), which generates the cluster beam, is complemented by three pick-up regions (chambers 2 and 3) in order to deposit reactants having different chemical natures at various places along the cluster beam. Two mass spectrometers (chambers 4 and 5) are used to characterize the cluster beam, according to procedures extensively described in Ref. [281]. The most important characterization is that of the average number of reactants deposited per cluster. Finally, two laser beams, a monochromator and a photon detection system are used to interrogate the reaction events through fluorescence measurements (chemiluminescence or laser-induced fluorescence).

The fate of the reaction product in cluster isolated chemical reactions

A series of studies by our group of the $\text{Ba} + \text{N}_2\text{O} \rightarrow \text{BaO} + \text{N}_2$ and $\text{Ba}_3 + \text{SF}_6 \rightarrow \text{BaF} + \dots$ reactions have led to the following scenario of CICRs [285, 294–298].

When a very exoergic, chemiluminescent reaction such as $\text{Ba} + \text{N}_2\text{O}$ takes place at the cluster surface, there is competition between ejection of the electronically excited product BaO from the cluster and its solvation. The reaction path of this

reaction is not much perturbed by the cluster and the chemiluminescence of the ejected product is very similar to that observed in the gas-phase reaction. In contrast, the cluster has a profound influence on the solvated product. It changes the branching to chemiluminescence, and affects the vibrational population of the electronically excited state.

From our work on the Ba–N₂O and Ba–SF₆ systems, a hierarchy in the degree of interaction between the cluster and the reaction product has been found. As just mentioned, the chemiluminescent product of very exoergic reactions is almost unaffected by the cluster. It is vibrationally and rotationally hot, presumably because it is ejected very rapidly after the reaction with not enough time to interact and to be cooled by the cluster. In contrast, free products, when electronically in the ground state, are also much colder rotationally and vibrationally, suggesting more interaction with the cluster [297]. As could easily be anticipated, the cluster effect is dramatic on the solvated products. Very strongly interacting clusters such as nitrogen clusters quench totally the chemiluminescence of the Ba + N₂O reaction. Instead, argon clusters, which interact much less with the product BaO*, do not quench its chemiluminescence. Nevertheless, within its lifetime, electronically excited BaO* is cooled vibrationally, down to $v = 0$. Only the less interacting neon clusters let BaO*, $v = 1$, be observed [286]. Finally, progressive embedding of the product BaO is reported, but this process turns out to be very slow. For instance, it takes place on a time-scale of a few tens of microseconds in neon clusters [298].

Electron-transfer reactions of barium and barium aggregates with oxidizing molecules

The CICR method has also been used to stabilize small barium aggregates (Ba₂, Ba₃, etc.), in order to explore their reactivity with oxidizing molecules ranging from very good to very poor oxidizing agents: Cl₂, O₂, CO₂ and SF₆ [283, 285, 293].

Multiple chemiluminescent channels are observed in the reaction of Cl₂ with barium dimers. They correspond to all the electronically excited products BaCl, BaCl₂ and Ba that are energetically accessible [293]. In contrast, only the most exoergic chemiluminescence channel corresponding to the formation of BaO is observed in the reaction of O₂ with Ba₂.

The most interesting results concern the reaction with the lesser oxidizing molecules, CO₂ and SF₆. Barium monomers do not react with these molecules at the cluster temperatures. This result is actually surprising considering that such reactions have been observed in the gas phase. Let us focus on the Ba + SF₆ reaction, which can be written as

Its energetics are deduced from Refs. [299, 300].

Process 30 has been studied in the gas phase using a crossed-beam apparatus [301]. The reaction product has not been clearly identified as being BaF or BaF₂, but its measured angular and velocity distributions reveal that the reaction proceeds via the formation of a long-lived BaSF₆ intermediate, which is believed to be the electron-transfer complex Ba⁺–SF₆[–]. Hence the reaction can be tentatively in-

Figure 20. Scheme of covalent and ion-pair curves describing the BaSF_6 , Ba_2SF_6 and Ba_3SF_6 systems. The construction details for these curves are given in Ref. [285].

interpreted on the basis of the harpoon model shown in Figure 20. The important point to observe is the crossing point between the ion-pair curve and the covalent curve. It is located at a short enough distance between Ba and SF_6 to experience the repulsive wall of the $\text{Ba} + \text{SF}_6$ covalent interaction. This leads to an activation barrier of about 0.1 eV height in the entrance channel of the reaction. We have already mentioned the existence of such barriers in electron-transfer reactions when considering the $\text{K} + \text{HCl}$ example in Section 2.7.1. However, this was a late barrier, which was overcome by vibrational excitation of the molecule. In the present $\text{Ba} + \text{SF}_6$ case, it is more probably an early barrier since it was overcome in the crossed-beam study of Herm et al. performed at 0.11 eV collision energy [301]. In the context of a CICR experiment on argon clusters, such a barrier blocks the reaction. The collision energy is then given by the cluster temperature and is too small (ca. 0.003 eV) to overcome the reaction barrier.

In contrast, $\text{Ba}_{\geq 2}$ aggregates react with CO_2 and $\text{Ba}_{\geq 3}$ aggregates react with SF_6 [283, 285]. This is exemplified in Figures 21 and 22 where the chemiluminescence of the barium- SF_6 system is considered. The chemiluminescence spectrum is shown in Figure 21 and the variation of its intensity is shown in Figure 22 as a function of the average number of both barium and SF_6 per cluster. It appears that only clusters carrying one SF_6 molecule and barium aggregates larger than Ba_3 lead to chemiluminescence. Hence chemiluminescence originates from reactions of one SF_6 molecule with $\text{Ba}_{\geq 3}$ aggregates.

The above results suggest that small barium aggregates are better reducing agents than atomic barium. This may be understood with the help of Figure 20, by considering that barium aggregates more easily transfer an electron in a redox reaction than barium atoms. Chevalyre and co-workers measured the ionization potentials

Figure 21. Chemiluminescence observed with Ba-SF₆ mixtures on argon clusters.

Figure 22. Chemiluminescence intensity as a function of the average number of barium atoms ($\langle m \rangle_{\text{Ba}}$, left) and SF₆ molecules ($\langle m \rangle_{\text{SF}_6}$, right) deposited per cluster. The curves show the variation of Poisson distributions of various orders as labeled.

of small barium aggregates and found 4.2, 4.0, 4.0 and 3.6 eV for Ba₂, Ba₃, Ba₄ and Ba₅, respectively, whereas the ionization potential of barium is 5.2 eV [302]. This leads to a larger distance for the electron transfer, and the lowering of the entrance barrier when switching from barium monomers to dimers, trimers, etc. The experi-

mental observation suggests that the barrier is low enough with $\text{Ba}_{\geq 3}$ to open the route to the electron transfer, and hence to the reaction.

2.9 Summary and Conclusions

The experimental and theoretical studies reported in this chapter have shown the central role of electron-transfers processes in the reactions of metals with oxidizing compounds. The electron-transfer process provides, at the transition-state level of the reaction, the driving force for the reactive evolution towards the products, as was first recognized by Polanyi [8]. In this framework, the reaction dynamics can be accurately described, and this is manifested in the recoil direction of the fragments and in the disposal of energy into the vibration and translation of the product of ionic character. The reaction mechanism via an electron transfer also applies to excited-state metals of higher ionization potentials, these excited-state metals being transformed by electronic excitation into open-shell facile electron donors. Further, excited-state reactions can produce excited-state products and this results from an electron transfer from excited covalent states to excited ion-pair potentials. Symmetry propensity rules correlate these excited-state reagents with the excited-state products.

The ion-pair potentials are usually one-dimensional and experiments have given recurring indications of their dependence on other coordinates (angular, for instance). As an example, the electron transfer needs an additional bond stretching for molecules having a negative electron affinity, as exemplified in the case of the $\text{K} + \text{CH}_3\text{I}$ reaction [69]. The ion-pair potentials that are used to interpret the experiments are mostly empirical; this follows from the difficulty of precise quantum chemical calculations for the diffuse negative ion. In this respect we can cite the case of $\text{Mg}^1\text{P}_1 + \text{H}_2$, where the electron transfer is readily identified with the saddle point for the 'insertion' reaction of Mg^* into H_2 [303]. This emphasizes the difficulty in assigning by quantum calculations the transition region of the reaction to an electron-transfer intermediate; the previous example involves H^- and hence has been more easily characterized. Thus we require developments in quantum calculations where charge analysis is performed; a recent example of this is the charge delocalization in clusters that involves a transfer of an electron from a metal to the solvent, and this process has been fairly accurately reproduced in the case of $\text{Na} + (\text{NH}_3)_n^-$ clusters, [304]. Similarly, there are few calculations describing accurately excited states; the example given by Truhlar and co-workers [75] on Na-HF is probably a singular case. Given the recent developments in calculations, it will be less of a challenge to perform them on excited states.

The observation of excited products in metal-molecule reactions is mostly limited to the simplest molecules. The formation of excited species is probably much more general and should be probed since the electron transfer can correlate excited-state reagents and excited-state products. In fact, the nascent excited-state products from reactions yielding complex polyatomic systems are quenched by nonadiabatic

transitions to the ground states of these molecules and remain unobserved except for special cases. These excited nascent states can be detected by femtosecond methods in the case of complex reagents but also in the case of excited-state reactions within clusters.

Solvation effects at the transition-state level of electron-transfer reactions is a field that is opening up by means of clusters reactions. Reactions within clusters (see Section 2.7) or at the surface of clusters (see Section 2.8) provide an experimental tool to observe the effect of gradual solvation on electron-transfer reactions. Femtosecond methods appear highly valuable for characterizing the electron transfer in reactions within clusters, since in neutral clusters the electrostatic effects of solvation will show up intensely at the electron-transfer level and for a short period of time, before the products are fully developed. In the gas phase the solvation of electrons is directly sensed by photoelectron spectroscopy, as exemplified in the (nonreactive) case of ultrafast solvation of electrons in water clusters [305].

The model of electron transfer in gas-phase metal-molecule reactions can be extended to more complex systems such as the collisions of metastable rare gas atoms with molecules to produce negative molecular ions [306]. In surface chemistry the harpoon model describes the forces between the reagents after the electron transfer has been applied to reactions of molecules with metal surfaces [120]. Another domain, involving the reaction of metal ions with complex systems could be interpreted in the framework of electron transfers: in the porphyrin site of the heme within hemoglobin, addition of oxygen to the Fe^{2+} results in an electron transfer from the metal to the oxygen. The dynamics of this attachment and of the photo-induced detachment could be viewed in that perspective.

In essence, electron transfer, characterized at the transition-state level of simple metal-molecule reactions, should provide a simple framework to study a variety of much more complex and important reaction mechanisms.

3 TICT Molecules

Jerzy Herbich and Bernhard Brutschy

3.1 Photoinduced Electron Transfer in Donor–Acceptor (D–A) Molecules in Solutions

3.1.1 Introduction

Excited-state electron transfer (ET) is a fundamental complex phenomenon playing a crucial role in a variety of photophysical, photochemical and biochemical reactions (for reviews see, for example, Refs. [1–3]). Owing to the essential role of ET in many processes and in photochemical applications (e.g., solar energy conversion and storage [4–6], photocatalysis [7], photopolymerization [8], information processing and storage [9] and photomedicine [10]) the understanding of the factors which determine the thermodynamics, kinetics and dynamics of the ET processes is very important.

Most investigations of photoinduced ET are performed in solutions. In this work the discussion of the excited-state ET is restricted to bichromophoric molecules where the donor (D) and acceptor (A) are formally linked by a single bond. In recent years, a large number and variety of D–A compounds have been characterized. These molecules can be classified into different families with respect to the angular relaxation of the D and A moieties. A class of these, which shows solvent-dependent characteristic dual fluorescence [11], is thought to form, upon excitation, a twisted intramolecular charge-transfer (TICT) state with an orbitally decoupled perpendicular geometry (the model was proposed by Grabowski and co-workers [12, 13]; see Sections 3.1.2 and 3.1.4). On the other hand, in larger D–A π -systems (which reveal non-negligible π – π interaction strongly depending on the torsional angle Θ_{A-D} between the planes of the A and D subunits) excited-state electron transfer can lead to a more planar mutual conformation [14] (see Section 3.1.3). Various processes which can occur upon excitation are summarized in Figure 1. Important issues related to the photophysics of such D–A systems are (i) the relative energy and interactions between the primary excited and charge-transfer singlet and triplet states ($^1,^3CT$), (ii) the electronic structure and conformation of the D–A molecules

Figure 1. Jablonski-type diagram of the lowest energy levels of electron donor–acceptor molecules formally linked by a single bond which show dual fluorescence phenomenon. D–A, $^1(D-A)^*$, $^1(D^+-A^-)$, $^3(D^+-A^-)$ and $^3(D-A)^*$ denote the ground state, the primary excited and charge-transfer (CT) singlet states, and CT and locally excited triplet states, respectively. The arrows correspond to the radiative (absorption, A, fluorescence, F, and phosphorescence, Ph) and the radiationless (internal conversion, IC, and intersystem crossing, ISC) processes.

in these states and (iii) the intramolecular and environmental factors controlling the kinetics and dynamics of the passage of electrons.

3.1.2 Solvent-dependent Dual Luminescence

A class of the electron D–A molecules shows a dual luminescence phenomenon [11]. The best known examples are *p*-cyano-*N,N*-dimethylaniline (CDMA) and its derivatives [11–13, 15–20], 4-dialkylamino derivatives of benzaldehyde and acetophenone [21, 22] and dialkylaminobenzoic acid esters [16, 23, 24] (Figure 2). The fluorescence originates from two different excited states (Figure 3). In nonpolar solvents and rigid low-temperatures glasses or for model systems constrained such that the electron-donating (dialkylamino) group lies in the plane of the aromatic acceptor ring, only a short-wave emission **b** is observed. An additional low-energy fluorescence band **a** is observed for the flexible molecules which have an internal degree of freedom for internal D–A rotation (e.g., CDMA) in a sufficiently polar and mobile environment or for compounds with a fixed, highly twisted conformation (e.g., TMCA) [12, 15].

The nature of this dual fluorescence phenomenon has been the subject of intense interest. The currently most widely accepted explanation assumes that dielectric polarization of the solvent permits excited-state rotational isomerization, leading to a highly polar fluorescent TICT state with a conformation of the D^+ and A^- moieties close to perpendicular [12, 13, 15–24]. This model predicts that the π -electronic decoupling of the D^+ and A^- subunits leads to full charge separation and, consequently, to a large dipole moment and a considerable solvent reorientational en-

Figure 2. Formulas of selected D–A compounds which contain 4-dialkylamino group as an electron donor and reveal dual fluorescence behaviour. Top: *p*-cyano-*N,N*-dimethylaniline (**I**, CDMA) and its model derivatives: *p*-cyano-2,6,*N,N*-trimethylaniline (**II**), *p*-cyano-2,6,*N,N*-tetramethylaniline (**III**, CTMA), *p*-aminobenzonitrile (**IV**, ABN) and 1-ethyl-2,3-dihydro-indole-5-carbonitrile (**V**, EIN). Middle: 4-(dimethylamino)pyrimidine (**VI**), 4-(diethylamino)pyrimidine (**VII**), 4-(dimethylamino)-5-methylpyrimidine (**VIII**), 4-(diethylamino)-5-methylpyrimidine (**IX**) and 4-(dimethylamino)-pyridine (**X**). Bottom: methyl 4-(dimethylamino)benzoate (**XI**, DMAMB), ethyl 4-(dimethylamino)benzoate (**XII**, DMAEB), *p*-(dimethylamino)-benzaldehyde (**XIII**) and *p*-(dimethylamino)acetophenone (**XIV**).

Figure 3. Schematic cross-section of the ground-state and the lowest excited singlet-state potential hypersurfaces along the reaction coordinate corresponding to the TICT state model (left, the reaction coordinate represented by the D–A twist angle) and exciplex model (right, the reaction coordinate represents the distance between reaction partners). The TICT state model proposes that dual fluorescence (**b** and **a**) is due to emission from the substrate (primary excited state B*) and product (A* \equiv TICT state) of the intramolecular excited state electron transfer (cf. Ref. [12]). E_{dest} is the energy difference between the Franck–Condon ground state and the solvent-equilibrated ground state. The term exciplex denotes a collision complex between the electronically excited species with any polar (or polarizable) ground-state molecule (cf. Refs. [28b, 29]). Donor and acceptor properties may be attributed to the reaction partners, since most exciplexes are stabilized by charge transfer interactions (ΔH denotes a stabilization enthalpy). Dual fluorescence, **M** and **E**, corresponds to the excited monomeric and exciplex species, respectively. The ground-state collision complexes are unstable (the Franck–Condon ground state is destabilized with respect to an equilibrated pair of molecules in the ground state by the repulsion energy δE_{rep}).

ergy. Dual luminescence is due to emission from the substrate (the primary excited B* state of low polarity; the conformation of the D–A molecule in this state is similar to that in the ground state [25]) and the product (A* \equiv TICT state) of the excited state intramolecular ET (Figure 3). The CT fluorescence carries a low electronic transition dipole moment, M_{flu} . This model has been adopted to explain the photophysical properties of the compounds related to the nucleic acid bases, such as 4-(dialkylamino)pyrimidines [26] and N^6,N^6 -dimethyladenosine [27].

An alternative intermolecular mechanism proposed by Chandross [30] and developed by Varma and co-workers [31] assumes that the long-wave emission *E* originates from solute–solvent exciplexes of CDMA (Figure 3). The binding between the polar nonaromatic solvent molecule and CDMA in the exciplex has been suggested to arise from local interactions with the solvent restricted to a single site in the solute (it has been proposed [31b] that the binding is due to an overlap between the lone pair orbitals on the solvent and the lone pair orbital on the amino nitrogen atom of the electronically excited CDMA). In aromatic solvents (e.g., benzene and toluene) a sandwich-like configuration of the 1:1 and 1:2 CDMA–solvent exciplexes has been proposed [31j]. Wang and Eisenthal [18b] attributed the

long-wave emission of CDMA in mixed solvents containing *n*-butanol to a complex between excited CDMA and an alcohol molecule. They postulated that in alcohol solutions the dominant stabilization of the fluorescent ^1CT state is due to a short-range specific interaction and a further stabilization of the complex occurs by a long-range polarization interactions with polar molecules. In view of the principal role of the solvent, a localized 1:1 solvation must be taken into account, at least in mixed solvents.

Still another explanation has been given by Zachariasse and co-workers [32]. According to this hypothesis, the CT fluorescence arises from vibronic coupling between closely spaced S_1 and S_2 (or S_3) states leading to a solvent-induced ‘pseudo–Jahn-Teller interaction’. In other words, a distortion of the molecule lowers its symmetry, permitting electronic coupling between the lowest excited singlet state, S_1 , and a higher one, S_i ($i = 2$ or 3), which has a large dipole moment. A solvent of high polarity would stabilize the dipolar component of the emissive state, hence increasing the mixing of the S_1 and S_i states. The reaction coordinate involves rehybridization of the amino nitrogen group from sp^3 to sp^2 and a deformation of the phenyl ring similar to that corresponding to radical anion formation of benzene.

It seems, in view of the experimental results, that the excited-state geometric rearrangement accompanying ET in the D–A amino compounds is complex and involves the twisting of the D and A moieties and the pyramidalization at the amino nitrogen; both effects have to be considered simultaneously. The systems which show dual fluorescence are very good models for theoretical studies trying to establish the links between structure and reactivity. The significance of the dimethyl-amino group torsion for ET in CDMA has so far not been proved; in fact, recent *ab initio* [33a–e] and semiempirical [15h, 26c, 33f–h] calculations of various quality confirm the TICT state model (the rehybridization coordinate seems to be less important). It has also been proposed [33i] that the distortion that lowers energy of the ^1CT state in this molecule is a bending of the $\text{C}=\text{C}\equiv\text{N}$ bond with respect to the ring and rehybridization of the cyano carbon atom from sp to sp^2 (RICT model). Such a bending would cause a stabilization of an intramolecular ^1CT state which is formed by transferring an electron from an aromatic π -orbital to the quasi- π^* -orbital of the cyano group. In recent and refined *ab initio* calculations by Sobolewski et al. [33e], however, the plausibility of the RICT model was not confirmed.

3.1.3 Electronic and Molecular Structure of Large D–A π -Systems

During the last three decades, ample experimental evidence has been accumulated which confirms that the photoinduced intramolecular electron transfer plays a key role in the photophysics of large D–A π -systems such as 9,9'-bianthryl (BA) [34–39], other biaryls [34d, 40] and their substituted analogues [41], aryl and heteroaryl derivatives of aromatic amines [42–50] and *N*-arylcarbazoles [51]. There is an important difference between the luminescence properties of the latter molecules and the former molecules containing 4-dialkylamino group as an electron donor (cf., Figure 2): the large D–A π -systems show single strongly allowed CT fluorescence at room temperature. Three of the most intriguing aspects of the photophysics of these

Figure 4. Left, radiative transitions in the inverted Marcus region: CT absorption (arrow up) and CT emission (arrow down). Right, schematic illustration of the relationship between radiative (diagonal arrows) and nonradiative (horizontal arrows) charge recombination in the inverted Marcus region. A quasi-continuum of the sublevels representing the low-frequency motions (mainly solvent modes) is associated with each quantized vibronic state, j , related to the high-frequency motions represented by a single 'averaged' mode characterized by ν_i . Charge recombination occurs from the lowest vibrational level ($j = 0$) of the initial CT state to the various vibrational sublevels (with $j = 0, 1, 2, \dots$) of the ground state. Adapted from Refs. [54b, 135].

D–A molecules relate to (i) the mechanism of the radiative and nonradiative charge recombination $^1\text{CT} \rightarrow \text{S}_0$, (ii) the electronic structure and conformation of the molecules in the fluorescent ^1CT state and (iii) the role of the charge-transfer triplet states (^3CT) in the intramolecular energy and electron transfer.

It has been shown recently by Kapturkiewicz and co-workers [14] that the analysis of the CT absorption $^1\text{CT} \leftarrow \text{S}_0$ and the radiative and radiationless charge recombination processes $^1\text{CT} \rightarrow \text{S}_0$ (Figure 4) in selected D–A π – π interacting systems sterically hindered to coplanarity (such as 9-anthryl and 9-acridyl derivatives of aromatic amines [14a,b], carbazol-9-yl derivatives of aromatic nitriles [14c] and ketones [14d] and D–A derivatives of indoles [14e] or phenoxazines and phenothiazines [14f]) in terms of the theory of photoinduced ET processes in absorption [52, 53] and emission [53–55] and Mulliken and Murrell models of molecular CT complexes [56, 57] leads to the determination of the quantities relevant for the rate of the radiative ET processes (exemplified by the CT absorption and emission) and to the estimation of the electronic structure and molecular conformation of the states involved in the photoinduced ET. A similar approach can be applied to describe the properties of the fluorescent singlet ^1CT states and phosphorescent triplet ^3CT states [58]. It should be pointed out that the relatively large values of the electronic transition dipole moments M_{flu} of the CT fluorescence indicate a non-

orthogonal geometry of the D and A subunits in the lowest ^1CT states of these compounds.

The time-dependent perturbation theory of the rates of radiative ET is based on the Born–Oppenheimer approximation [59] and the Franck–Condon principle (i.e. on the separation of electronic and nuclear motions). The theory predicts that the ET rate constant, k_{ET} , is given by a ‘golden rule’-type equation, i.e., it is proportional to the product of the square of the donor–acceptor electronic coupling (V) and a Franck–Condon weighted density of states (FC):

$$k_{\text{ET}} = \frac{4\pi^2}{h} V^2 (FC) \quad (1)$$

A challenging problem for large organic solute–solvent systems is the accurate evaluation of the FC term. An analysis of the CT absorption (Eq. 2 [14a–c, 52, 53]) and emission spectra (Eq. 3 [14, 53–55]), within the semiclassical approach employing a single intramolecular quantized mode yields the reaction driving force (the Gibbs free energy of the CT process, ΔG_{CT} , Figure 4) and estimates the low-frequency (λ_o) and the high-frequency (λ_i) reorganization energies, and the average energy spacing ($h\nu_i$) of the effective quantized mode undergoing reorganisation upon electron transfer:

$$\frac{\varepsilon(\tilde{\nu}_a)}{n\tilde{\nu}_a} = \frac{8\pi^3}{3c \ln 10} M_{\text{abs}}^2 \sum_{j=0} \frac{e^{-S} S^j}{j!} \sqrt{\frac{1}{4\pi\lambda_o k_B T}} \exp \left[-\frac{(jh\nu_i + \lambda_o - hc\tilde{\nu}_a + \Delta G_{\text{CT}})^2}{4\lambda_o k_B T} \right] \quad (2)$$

$$\frac{I(\tilde{\nu}_f)}{n^3 \tilde{\nu}_f^3} = \frac{64\pi^4}{3h} M_{\text{flu}}^2 \sum_{j=0} \frac{e^{-S} S^j}{j!} \sqrt{\frac{1}{4\pi\lambda_o k_B T}} \exp \left[-\frac{(jh\nu_i + \lambda_o + hc\tilde{\nu}_f + \Delta G_{\text{CT}})^2}{4\lambda_o k_B T} \right] \quad (3)$$

where S is the electron–vibration coupling constant:

$$S = \lambda_i / h\nu_i \quad (4)$$

and where electronic transition dipole moments of the CT absorption (M_{abs}) and CT fluorescence (M_{flu}) may depend, in principle, on the wavenumber $\tilde{\nu}_a$ and $\tilde{\nu}_f$ of the absorption and emission, respectively. $\varepsilon(\tilde{\nu}_a)$ is the molar CT absorption coefficient for photons with energy $hc\tilde{\nu}_a$. $I(\tilde{\nu}_f)$ denotes the CT fluorescence intensity, i.e., the rate of the emission of photons with energy $hc\tilde{\nu}_f$ expressed in photons per molecule per unit time per unit spectral energy [integration of $I(\tilde{\nu}_f)$ over the whole range of $\tilde{\nu}_f$ leads to the radiative rate constant k_f]. n and T are the refractive index of the surrounding medium and temperature, respectively. k_B , h and c are the Boltzmann and Planck constants and the speed of light, respectively. The reorganization energy λ_o is related to the low-frequency motions such as reorientation of the solvent shell (λ_s) as well as any other low-frequency ($\tilde{\nu}_L < 200 \text{ cm}^{-1}$) and

medium-frequency ($\tilde{\nu}_M \approx 300\text{--}600\text{ cm}^{-1}$ [14c, 55]) nuclear motions of the solute ($\delta\lambda_o$). The inner reorganisation energy λ_i corresponds to the high-frequency motions (represented by a single 'averaged' mode ν_i) associated with the changes in the solute bond lengths and angles.

The electronic coupling elements between the lowest excited ^1CT state and the ground state (V_0) or the locally excited state lying most closely in energy (V_1) can be estimated from the CT absorption and fluorescence investigations [14, 54, 57]. Applying a simple kinetic model of an irreversible excited CT state formation (with 100 % efficiency) the radiationless (k_{nr}) and radiative (k_{r}) rate constants can be determined from the CT fluorescence quantum yields Φ_{f} and lifetimes τ :

$$k_{\text{nr}} = (1 - \Phi_{\text{f}})/\tau \quad (5)$$

$$k_{\text{r}} = \Phi_{\text{f}}/\tau \quad (6)$$

and the resulting electronic transition dipole moments M_{flu} are given by [60]

$$k_{\text{r}} = \frac{64\pi^4}{3h} (n\tilde{\nu}_{\text{flu}}^{\text{CT}})^3 |M_{\text{flu}}|^2 \quad (7)$$

The electronic transition dipole moments M_{abs} corresponding to the CT absorption can be determined from an approximate expression [60]

$$|M_{\text{abs}}|^2 = \frac{3 \ln 10}{8\pi^3 N_{\text{A}}} \frac{hc}{n\tilde{\nu}_{\text{abs}}^{\text{CT}}} \int_{\text{band}} \varepsilon(\tilde{\nu}_{\text{a}}) d\tilde{\nu}_{\text{a}} \quad (8)$$

where $\tilde{\nu}_{\text{abs}}^{\text{CT}}$ is the wavenumber of the CT absorption maximum and N_{A} is Avogadro's number.

The comparison of the M_{flu} values with those of M_{abs} allows one to obtain information about the changes in the electronic structure and molecular conformation between the Franck–Condon excited state initially reached upon excitation and the solvent-equilibrated fluorescent state [14]. Electronic transition dipole moments are mainly determined by the direct interactions between the lowest ^1CT state and the ground state (S_0), and by the contributions from the locally excited configurations [14, 54, 56, 57]. For example, for the fluorescent ^1CT state one can obtain

$$M_{\text{flu}} \approx \frac{V_{0\text{F}}(\vec{\mu}_{\text{e}} - \vec{\mu}_{\text{g}})}{hc\tilde{\nu}_{\text{flu}}^{\text{CT}}} + \sum_i \frac{V_{i\text{F}}\vec{M}_i}{E_i - hc\tilde{\nu}_{\text{flu}}^{\text{CT}}} \quad (9)$$

where $hc\tilde{\nu}_{\text{flu}}^{\text{CT}}$ is the energy of the solvent-equilibrated CT fluorescence maxima, $\vec{\mu}_{\text{g}}$ and $\vec{\mu}_{\text{e}}$ are the dipole moments of the D–A molecule in the ground and excited state, respectively, and $V_{0\text{F}}$ and $V_{i\text{F}}$ denote the electronic coupling elements between the fluorescent ^1CT state and the ground state or the locally excited (^1LE)_{*i*} states, respectively. The first term in Eq. 9 is related to the Mulliken two-state model [56a] (i.e., the direct interactions between the fluorescent ^1CT state and the Franck–

Condon ground state) and the second term represents the Murrell ‘borrowing’ mechanism [56b] [i.e., the contributions from the $(^1\text{LE})_i$ states of energy E_i]. The electronic transition dipole moments M_i correspond to the radiative transitions $(^1\text{LE})_i \rightarrow S_0$. The above relation allows one to estimate the values of the electronic coupling elements V_{0F} and V_{1F} (i.e., between the fluorescent ^1CT state and the locally excited state lying most closely in energy). The matrix elements V_{0A} and V_{1A} corresponding to the Franck–Condon excited CT state reached in absorption can be estimated from a relation analogous to Eq. 9 [14].

An interesting challenge in the study of the intramolecular electron-transfer reactions is to identify structural elements that promote electronic coupling between an electron donor and an acceptor. It has been shown by Kapturkiewicz and co-workers [14] that the appropriate values of the electronic coupling elements, which are mainly determined by the interactions between the atoms forming the A–D bond, can be theoretically predicted following the formalism proposed by Dogonadze et al. [61]. Neglecting contributions from the σ -orbitals, one can obtain for π -electronic systems [14]

$$V_0 = C_{\text{LUMO}}^{\text{A}} C_{\text{HOMO}}^{\text{D}} \beta_{\text{AD}} \cos(\Theta_{\text{A-D}}) + \text{constant} \quad (10a)$$

$$V_1^{\text{A}} = C_{\text{HOMO}}^{\text{A}} C_{\text{HOMO}}^{\text{D}} \beta_{\text{AD}} \cos(\Theta_{\text{A-D}}) + \text{constant} \quad (10b)$$

$$V_1^{\text{D}} = C_{\text{LUMO}}^{\text{A}} C_{\text{LUMO}}^{\text{D}} \beta_{\text{AD}} \cos(\Theta_{\text{A-D}}) + \text{constant} \quad (10c)$$

where $\Theta_{\text{A-D}}$ denotes the angle between the planes of the A and D subunits, C_{HOMO} and C_{LUMO} are the LCAO coefficients (as obtained for the individual chromophores) of the $2p_z$ atomic orbitals (where z is the axis perpendicular to the acceptor or donor rings) of the highest occupied molecular orbital (HOMO) and of the lowest unoccupied molecular orbital (LUMO) located on the atoms forming the A–D bond, β_{AD} is the resonance integral for these atoms and the constant is related to the electronic interactions between the remaining pairs of atoms in the D–A molecule (this contribution is usually small and negligible because β_{AD} is an exponential function of the distance). Expressions 10b and 10c assume that the locally excited ^1LE state which interacts with the ^1CT state and is localized either in the acceptor or in the donor subunit, respectively, is mainly described by a configuration corresponding to the HOMO \rightarrow LUMO excitation (e.g., $^1\text{L}_a$ state in Platt’s notation).

The studies reported in Refs. [14a–f] show that the conformation of the investigated D–A systems in the fluorescent ^1CT states (and its dependence on the solvation effects) can be explained in terms of a simple model assuming the competition between: (i) the stabilization of the highly polar ^1CT state by a polar surrounding (this could lead to the decoupled perpendicular conformation, i.e. the TICT state, of the molecule resulting from the large dipole moment due to the full electron transfer), (ii) the stabilization effects related to the electronic interactions between the donor and acceptor subunits (these could result in the planar conformation of the molecule) and (iii) the steric repulsion between both moieties. For example, 9-anthryl and 9-acridyl derivatives of aromatic amines, as has been suggested by Mataga and co-workers [42], show the dependence of the electronic structure and conformation of the fluorescent ^1CT state on solvation [47]. In a low-

polarity environment, the interactions between the ^1CT state and the locally excited states (mainly with the $^1\text{L}_a$ state localized on the acceptor ring) lead to a more planar mutual conformation (of $\Delta\Theta_{\text{A-D}} \approx 15\text{--}20^\circ$) of the D and A moieties than that in the ground state [14a,b]. In highly polar solvents the relatively strong solute–solvent interactions prevent the flattening of the excited D–A system and its conformation is similar to that in the ground state. It has been also shown that the angle $\Theta_{\text{A-D}}$ in the fluorescent ^1CT state of N-bonded D–A derivatives of 3,6-*di-tert*-butylcarbazole containing benzonitrile, nicotinonitrile or various dicyanobenzenes [14c] and ketones [14d] as an electron acceptor, and also of the D–A systems containing indole [14e] and phenothiazines and phenoxazines [14f] as an electron donor, do not change the geometry significantly upon excitation.

3.1.4 TICT Molecules

The influence of *o*-methylation on the photophysical properties of the molecules which show dual luminescence phenomenon (Figure 2) and the low electronic transition dipole moments, M_{flu} , corresponding to the $^1\text{CT} \rightarrow \text{S}_0$ transition, and also the large dipole moments, μ_e , of the fluorescent ^1CT states indicate a small overlap between the donor (i.e., the lone pair orbital on the amino nitrogen) and the acceptor π -orbitals. The determined values of M_{flu} do not correspond, however, to an orthogonal molecular geometry. The large energy gap (especially in polar solvents) between the fluorescent ^1CT state and the lowest $^1(\pi, \pi^*)$ state of the acceptor subunit such as benzonitrile (which lies about $36\,000\text{ cm}^{-1}$ [62a]), pyrimidine ($40\,000\text{ cm}^{-1}$ [62b,c]), pyridine ($38\,000\text{ cm}^{-1}$ [62b,c]), methyl benzoate ($35\,600\text{ cm}^{-1}$ [62d]) and acetophenone ($35\,000\text{ cm}^{-1}$ [62e]), strongly suggests that the first term in Eq. 9 is dominant in the description of the CT fluorescence of the compounds shown in Figure 2. Neglecting the second term in Eq. 9, one obtains $V_0 \approx 0.18\text{ eV}$ for 4-(dimethylamino)-5-methylpyrimidine (**VIII**) in acetonitrile from the data collected in Table 3 in Ref. [26c]. Following the discussion presented in Section 3.1.3, one can estimate the mutual conformation of the D (dimethylamino group) and A (pyrimidine ring) subunits (i.e., the angle $\Theta_{\text{A-D}}$ between the axis, z , perpendicular to the acceptor ring and the axis of the lone pair orbital, l , located on the amino nitrogen atom N_a):

$$V_0 = C_{\text{LUMO}}^{\text{A}} C_{\text{HOMO}}^{\text{D}} \beta_{\text{CN}} \cos(\Theta_{\text{A-D}}) + \text{constant} \quad (10\text{d})$$

where $C_{\text{LUMO}}^{\text{A}}$ and $C_{\text{HOMO}}^{\text{D}}$ are the LCAO coefficients of the $2p_\pi$ atomic orbitals located on the carbon atom and of the l orbital on the adjacent N_a atom of the LUMO and the HOMO, respectively and β_{CN} is the resonance integral for these atoms which form the A–D bond. The values of $C_{\text{LUMO}}^{\text{A}} \approx 0.56$ and $C_{\text{HOMO}}^{\text{D}} \approx 0.87$ were calculated by the INDO/S method [26c] for the perpendicular conformation of **VIII**. Assuming $\beta_{\text{CN}} = 2.3\text{ eV}$ [63], one can estimate the angle $\Theta_{\text{A-D}}$. The values of 81° (constant = 0) and 84° (constant = 0.06 eV , as taken from the investigations of the carbazol-9-yl derivatives of aromatic nitriles [14c]) can be regarded as the lower and upper limits. Thus, the conformation of these relatively small compounds

Figure 5. Resonance structures of the zwitterionic forms of 4-(dimethylanilino)pyrimidine.

containing dialkylamino group as an electron donor in the fluorescent ^1CT state is nearly orthogonal (most probably because of the strong solute–solvent interactions which in the theory of continuum polarization depend on the magnitude of the ratio μ_e^2/a_o^3 , where a_o denotes the effective radius of the Onsager cavity [64]). The small deviation from perpendicularity is due to the effects related to the electronic delocalization from the lone-pair orbital on the amino nitrogen to the acceptor ring.

The photophysical behavior of these compounds turned out to be very different from that of the conjugate donor–acceptor π -systems such as 4-(dimethylanilino)-pyrimidine (4-DAAP) [26c] and other D–A biphenyl derivatives [65]. In contrast to the TICT state model, the CT fluorescence of 4-DAAP is strongly allowed. Absorption and luminescence of the compound indicate that the conformation of both the Franck–Condon state initially reached upon excitation and the solvent equilibrated fluorescent state is similar and close to planarity. Owing to the large π -overlap, mesomeric interaction between the donor and acceptor subunits (Figure 5) is significant, and the excitation can involve only a partial charge transfer.

3.2 Supersonic Jet Spectroscopy of Selected D–A Molecules

3.2.1 Introduction

Most investigations of photoinduced electron transfer have been performed in condensed phases. Much less is known about conditions that permit the occurrence of intramolecular ET in isolated (collision-free) molecular D–A systems. A powerful method for this kind of study is the supersonic jet expansion technique (which was originally developed by Kantrowitz and Grey in 1951 [66]) combined with laser-induced fluorescence (LIF) spectroscopy and time-of-flight mass spectrometry (TOF-MS). On the other hand, the molecular aspects of solvation can be studied by investigations of isolated gas-phase ‘solute–solvent’ clusters which are formed in a supersonic jet expansion [67] (jet cooling under controlled expansion conditions [68] permits a stepwise growth of size-selected solvation clusters [69–71]). The formation of van der Waals complexes between polyatomic molecules in a supersonic jet pro-

vides a way to study exciplex [72–77] and excimer [78, 79] formation in a gas phase (see Chapter IV.3.4). Crossing from an excited state of a van der Waals complex to the exciplex at low excess of excitation energy has been discussed by Deperasińska and Prochorow [80]. Studies of electron D–A molecules such as CDMA (Figure 2) and its derivatives [81–92], dialkylaminobenzoic acid esters [82d, 85, 88, 91–95], 4-(dialkylamino)pyrimidines [90, 92d], 9,9'-bianthryl [96–98], 4-(9-anthryl)-*N,N*-dimethylaniline (ADMA) [99], 4-(9-anthryl)aniline (AA) [100], 9-(*N*-carbazolyl)-anthracene [101] and 4-(carbazol-9-yl)benzonitrile [86e, 102] in a free jet expansion have attempted to investigate the properties and significance of isolated molecules and their complexes with polar and/or protic partners with respect to CT emission.

The conditions for photoinduced charge separation and recombination in solvent-free molecules have recently been analyzed theoretically by Jortner et al. [103]. The important factors that could lead to intramolecular ET are (i) sufficiently large electronic coupling V and significant Franck–Condon vibrational overlap factors between the excited state $^1(\text{D-A})^*$ and the vibronic state of the $^1\text{CT} (\text{D}^+-\text{A}^-)$ manifold (Figure 6) and (ii) a large density of effectively coupled vibronic levels

Figure 6. Schematic molecular level structure for electron transfer processes in an isolated molecule. Excitation $S_0(\text{D-A}) \rightarrow S_2[(\text{D-A})^*]$ selects the vibronic level(s), which undergo(es) intramolecular charge separation (denoted by horizontal arrow) to the $S_1(\text{D}^+-\text{A}^-)$ vibronic manifold quasi-degenerate with it. Excitation $S_0 \rightarrow S_1$ selects the vibronic levels of the charge-transfer singlet state, which undergo intramolecular charge recombination (denoted by a horizontal arrow) to the ground-state vibronic manifold. Radiative electron transfer exemplified by the CT fluorescence is labeled with a broken arrow. Adapted from Refs. [103a–d].

(this situation could be realized for a sufficiently large electronic energy gap ΔE between the origins of the two interacting states). Excited-state electron transfer in jet-cooled bare molecules has been already reported for a few cases of D–A molecules {such as CTMA [81b, 90a] and (*p*-cyanophenyl)pentamethyldisilane [104]} and donor–bridge–acceptor (D–B–A) systems [73i, 105–108].

The supersonic jet expansion technique generates ‘supercooled’ species: translational and rotational ‘temperatures’ could be as low as 0.5 K, vibrational ‘temperatures’ are higher [68]. Jet cooling decongests an otherwise dense spectrum of the solute molecule. The cooling and a consequent spectral simplification offer a chance to study the structural changes and the dynamics of the excited-state processes. For example, the application of high-resolution LIF spectroscopy and/or resonance-enhanced multiphoton ionization mass spectrometry (REMPI-MS) [109] allows one to probe the structures via rotational band-contour analysis [86–89, 90c,d, 92b, 95, 97–101], to identify alternative intramolecular conformers {e.g., via the stimulated emission pumping (SEP) technique [110]} and cluster geometries and to explore the dependence of solvent-induced spectral shifts on both the nature and the local structure of the solute–solvent cluster.

This section describes the application of high-resolution LIF spectroscopy combined with REMPI-TOF-MS to probe the conditions that permit the occurrence of electron transfer in the excited state of isolated bare molecules and also in their size-selected microsolvated clusters (in order to assess the incidence of solvent molecular perturbations in a controlled manner). A schematic diagram of the supersonic beam apparatus, developed by Brutschy and co-workers [92], is shown in Figure 7. The equipment was described in detail in Ref. [92a]. Briefly, with helium as the carrier gas, the chromophore and solvent molecules are expanded by a pulsed solenoid valve with a nozzle diameter of 500 μm into two differentially pumped, sequentially aligned vacuum chambers, which are connected via a 5.0 mm diameter skimmer. The sample is heated in an oven very near to the nozzle to achieve sufficient vapor pressure. The low-pressure solvent vapor is mixed with the carrier gas before introducing it into the nozzle. Its amount is controlled with needle valves regulating the flow conditions and by the temperature of the solvent reservoir. UV excitation is provided by the pulsed, frequency-doubled output of an Nd:YAG pumped optical parametric oscillator (OPO) (Continuum, Sunlite) tunable within the range 450–710 nm. The bandwidth of the laser running at a repetition rate of 10 Hz is about 0.1 cm^{-1} and the pulse width is about 8 ns. In chamber 1 (expansion chamber) the molecules and clusters are excited by laser radiation in order to observe the dispersed emission spectra. Fluorescence is collected at a right-angle to both the jet and the laser beam, dispersed by a spectrograph (Chromex 250 IS with 1200 and 300 grooves mm^{-1} gratings) and detected with a CCD camera coupled to an image intensifier (LaVision, FL-III). In chamber 2, the molecules and clusters are ionized by one-color resonant two-photon ionization (1C-R2PI) via a resonant excitation into the S_1 vibronic manifold and a non-resonant second step into the ionization continuum. Subsequently, the ions are mass analyzed in a reflectron TOF mass spectrometer equipped with a microchannel plate detector and a digital oscilloscope. A variable time delay between laser pulse and valve opening pulse is used to ensure that the same portion of the inhomogeneous gas pulse is probed for the dis-

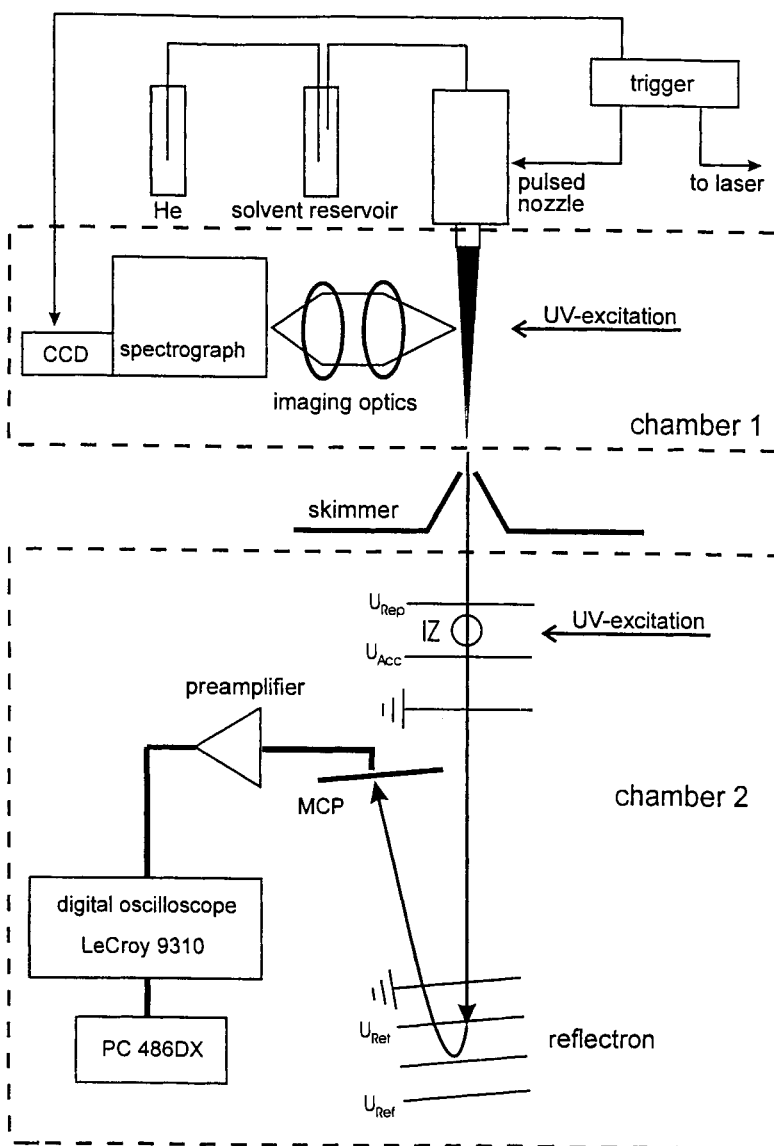

Figure 7. Schematic diagram of the supersonic beam apparatus which combines laser-induced fluorescence spectroscopy with time-of-flight mass spectrometry. Reproduced with permission from Ref. [92a].

persed emission spectrum in the first chamber and for the cluster size analysis in the second chamber (correction of flight time between the two chambers).

The present discussion is restricted to D-A molecules which show dual fluorescence in solutions, i.e., 4-dialkylamino derivatives of benzonitrile (**I–III**, Figure

2), pyrimidine (VI–IX) and benzoic acid esters XI, XII (the investigations of larger D–A π -systems, such as ADMA, are reviewed in Chapter IV.3.5). The main variables in the studies were (i) the conformation of the ground-state molecule, being close to planarity (I, VI, VII, XI, XII) or ‘pretwisted’ due to the *o*-methylation in the acceptor ring (II, III, VIII, IX) and (ii) the use of different solvent partners (e.g., water, methanol, tetrahydrofuran, acetonitrile). It is known from X-ray investigations [25] that for CDMA (I) and CTMA (III) the torsional angle between the dimethylamino group and acceptor ring is 10° and 59.3° , respectively (the amino nitrogen atom deviates slightly from the plane of the acceptor ring). The photo-physical behavior of the TICT molecules has been compared with that of the model compounds such as ABN (IV) and EIN (V) which do not show the CT fluorescence band in solutions. 4-(Dialkylamino)pyrimidines (VI–IX) seemed to be an attractive family of D–A molecules to study the influence of hydrogen bonding on the ET processes.

3.2.2 Bare Molecules

In recent years, the study of D–A molecules containing the dialkylamino group as an electron donor in supersonic jet conditions has received considerable interest. Particularly extensive investigations have been performed for CDMA (I) and its derivatives (e.g., II–V). It has been reported by Kobayashi et al. [81a], Phillips and co-workers [82], Peng et al. [83] and Bernstein and co-workers [84] that jet-cooled I did not show the excited ^1CT state formation. Figure 8 presents LIF emission and excitation spectra of I and its two *o*-methylated derivatives (II, III) [90a]. Compounds I [81a, 82, 83, 85, 86, 88–91] and II [90] exhibit the structured LIF excita-

Figure 8. Left, LIF emission spectra and right, LIF excitation spectra of jet-cooled I, II and III [90]. The fluorescence spectra were recorded with a spectral resolution of the detection monochromator of 10–15 nm (the position of excitation is indicated by an asterisk). The detection wavelength for the excitation spectra was 340 nm (I and II) or 400 nm (III).

tion spectra (and very similar R2PI-TOF mass spectra [84, 87a, 92a,b]). The excitation spectrum of **III** is diffuse. A possible explanation of the diffuseness is the broadening of the individual lines as a result of a short lifetime of the optically excited state caused by rapid vibrational redistribution (IVR) and/or internal conversion (IC). Emission spectra of the compounds have been recorded with low resolution of the detection monochromator [90a,b], hence they are structureless. The relatively narrow fluorescence of **I**, which is centered at about 330 nm, has been assigned to a nearly planar delocalized state **B*** (cf. Figure 3). On the other hand, the fluorescence of CTMA is markedly broader and red shifted. The shape and position of the emission of **III** in a thermalized vapor [15d] and in a supersonic jet [81b] depend on the excitation (higher energy excitation leads to the blue shift of the fluorescence maximum). The emission was found to be composed of two transitions: first, **a** (Figure 3), from the ^1CT state, and the second, **b**, from a higher excited $^1(\pi, \pi^*)$ state. The long-wave emission $^1\text{CT} \rightarrow \text{S}_0$ dominates upon direct excitation to the ^1CT state and the intensity of the short-wave emission $\text{S}_2(^1\pi, \pi^*) \rightarrow \text{S}_0$ increases with excess excitation energy.

The shape and position of the LIF emission spectrum of **II** as a function of the excitation energy has been examined [90, 92d]. The molecule has been excited up to 4400 cm^{-1} above the 0,0 transition. As can be seen in Figure 9, the maximum shifts to the red and the half-width of the spectrum increases markedly (from 4900 to 6800 cm^{-1}) with excess excitation energy. However, no distinct shoulder was found in the expected region of the CT emission (comparison of the spectra of **II** and CTMA leads to the conclusion that the ^1CT state is not markedly populated in **II**). In this respect the behavior of **II** is similar to that of CDMA: (i) no evidence for the CT emission from **I** could be found upon excitation up to 4500 cm^{-1} above the electronic origin [82d, 83], and (ii) the half-width of the spectrum increases with excitation energy. Increasing the excitation energy could give rise to a red shift and broadening of the dispersed emission when the vibrational frequencies are smaller in the excited electronic state than those in the ground state. The diffuseness of the spectrum is due to the diversity of these frequency shifts since, as a result of IVR, the emission originates from a number of vibronic levels. The red shift and broadening of the emission from **II**, observed with increasing excess excitation energy, is relatively strong with respect to the magnitude of these effects for molecules of similar size. Such behavior can occur if the emitting vibronic states contain vibrational modes with strongly reduced frequencies in the upper electronic state. The torsional and inversion modes of the dialkylamino group could act as such vibrations.

Similarly to CDMA and **II**, and in contrast to CTMA, the LIF excitation spectra for the other molecules considered (i.e., ABN [86, 92b], EIN [92b], 4-dialkylamino derivatives of pyrimidine (except **VIII**) [90] and benzoic acid esters, **XI** and **XII** [88, 91, 94]) show the characteristic pattern of low-frequency vibrations (Table 1). Similar patterns have been analyzed for alkylbenzenes and toluenes [111], fluorotoluene [112, 113a,b], *m*-cresol [113c], toluidines [113d] and dialkylanilines [87a, 114] in terms of the internal rotation of the methyl groups, torsion of the dialkylamino group and inversion. The precise nature of the vibrations active in the LIF spectra of the considered compounds is not yet clear, but it is most probably associated with torsion and inversion of the dialkylamino group [86, 87, 88b, 90c]. The lowest

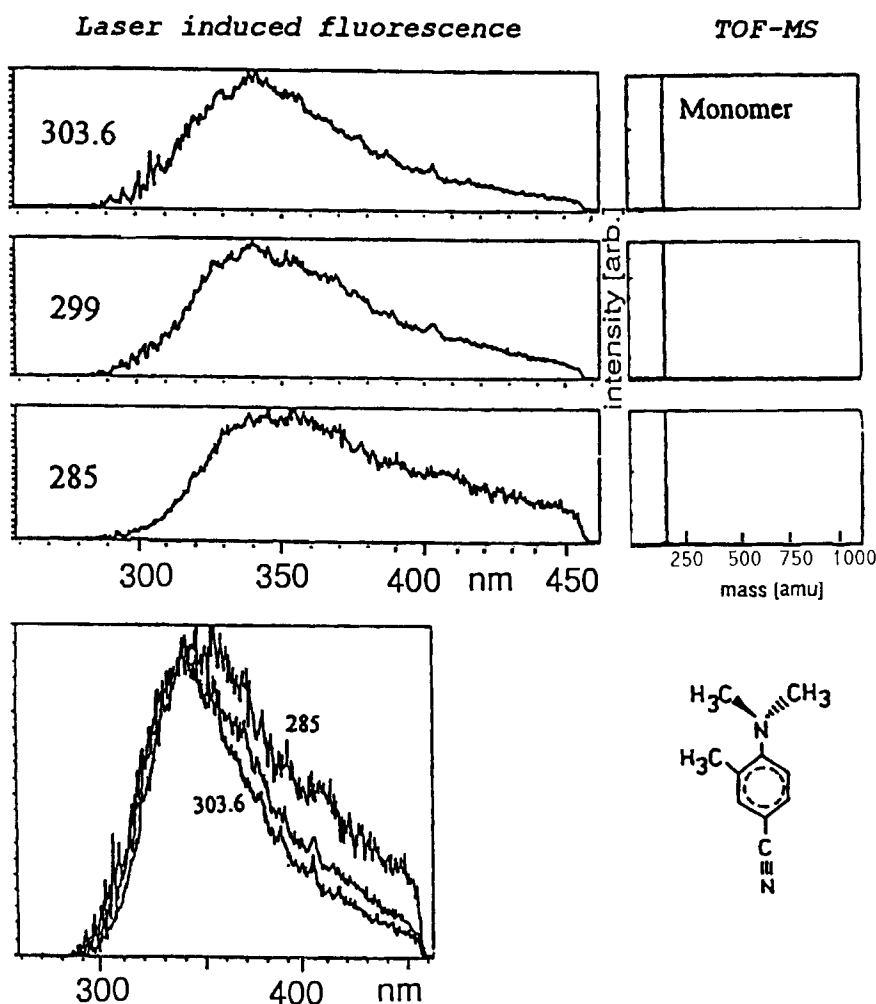

Figure 9. Effect of increasing the excess excitation energy on the LIF spectra of **II** in a supersonic jet expansion. TOF mass spectra (right) indicate that the emission spectra (left, bottom) correspond to the monomer. The numbers indicate the wavelengths of excitation (in nm).

energy transitions of the excitation spectra were assigned to the 0,0 transition, in spite of their weakness. The low intensity of the first vibronic band and the progression of the low-frequency vibrations suggest a change of the geometry of the compounds in the fluorescent states with respect to that in the ground state.

Analysis of the vibrational structure and rotational contours of the LIF emission and excitation spectra offers the possibility of studying the conformational changes of the molecules and clusters upon excitation. However, the assignment of the low-frequency modes observed in the LIF excitation spectra of the investigated compounds is difficult in view of the complexity of the dialkylamino group which may

Table 1. Spectral position of the origin ($\tilde{\nu}_{\text{vac}}$ in cm^{-1}) and the vibrational bands observed in the LIF excitation spectra of the monomers of CDMA (**I**, Figure 2), its *o*-methylated derivative (**II**) and 4-(dialkylamino)pyrimidines (**VI**, **VII** and **IX**) in the supersonic jet expansion^{a,b,c}

^a Accuracy of results: $\pm 0.5 \text{ cm}^{-1}$ [90a,b].^b A, B, C and M (\equiv mixed) denote the type of rotational contour [90c,d].^c The positions of the vibrational transitions obtained by IC-R2PI-TOF-MS [92] are very similar to those given in this Table.

undergo *N*-aryl torsion, *N*-methyl rotation and inversion. Microwave investigations of dimethylaniline (DMA) [115a] provide an estimate for the frequency of the NMe_2 group torsion about the *N*-aryl bond; the torsional frequency appears to be less than 100 cm^{-1} . The frequency of *N*-methyl rotation is expected to be somewhat higher. Its value is about 257 cm^{-1} in dimethylamine [116] (the barrier to this motion in *N*-methylaniline [115b,c] has been estimated to be comparable to that in dimethylamine). The torsional barrier in DMA is expected to be higher than that in *N*-methylaniline. On the basis of the above information, the lowest energy vibronic

transitions in the LIF excitation spectra of the studied compounds seem to be associated with torsion and inversion of the dialkylamino group [86, 87]. Assuming that the pattern of seven low-frequency transitions in the vicinity of the electronic origin of the LIF excitation spectrum of CDMA corresponds to the progressions of the NMe₂ group torsion and inversion, and using a Franck–Condon intensity analysis, Grassian et al. [87a] determined that the D–A twist angle (Θ_{A-D}) in the excited state is about 30° ($\Theta_{A-D} = 0^\circ$ in the ground state has been assumed). On the other hand, the effects of deuterium on the vibrational structure of the LIF spectra of DMA [94] and diethylaniline (DEA) [114] led Weersink and Wallace to the assignment of the low-frequency bands to the *N*-methyl or *N*-ethyl rotation, respectively.

Rotational contour analysis of the number of vibrational transitions in **I**, **II**, **VI**, **VII** and **IX** has been performed by Pérez Salgado et al. [90c,d]. For CDMA most bands near to the origin are of B-type rotational contour [86, 88, 89, 91, 92b], indicating that the electronic transition dipole moment is polarized along the short in-plane molecular axis (i.e., it is the $^1L_b \leftarrow S_0$ transition as in aniline [117] and benzonitrile [118]). The simulation procedure of these contours (which is based on the asymmetric-top rigid-rotor approximation [119] and assumes the separation of the rotational and vibrational motions) suggests that jet-cooled **I** undergoes small changes in conformation upon excitation. Kajimoto et al. [89] and Lommatzsch and Brutschy [92b] (Figure 10) reported that this analysis leads to a torsional angle between the donor and acceptor moieties in the fluorescent state of $\Theta_{A-D} \approx 20\text{--}30^\circ$. Concerning the inversion potential, the most stable conformations have been found [89] to correspond to the angles 15° and 0° for the ground and excited state, respectively. The rotational contour analysis for several vibronic bands in the first 250 cm^{−1} range above the origin of the LIF excitation spectra of 4-(dialkylamino)pyrimidines (**VI**, **VII** and **IX**) reflects the complex spectroscopy of these compounds [90c]. In contrast to CDMA and **II**, and similarly to pyrimidine [120], the 0,0 transition of **VI** exhibits a mixed-type of rotational contour with a dominant contribution of the C-type transition (which is characteristic for the out-of-plane polarized electronic transitions [e.g., $^1(n, \pi^*) \leftarrow S_0$]). On the other hand, **VII** and **IX** show mainly A-type transitions, i.e., polarized along the long in-plane axis. The simulation of the rotational contours suggests that the conformation of these molecules is similar to that in the ground state.

The lack of mirror symmetry between the LIF excitation spectra and high-resolution dispersed fluorescence spectra of CDMA upon 0,0 excitation (i.e. excitation into the lowest energy band centered at 310.022 nm) has been observed [90c,d]. Excitation into the origin and of the single vibronic levels such as 0,0 + 76 cm^{−1}, 0,0 + 113 cm^{−1}, 0,0 + 136 cm^{−1} and 0,0 + 176 cm^{−1} (Table 1) leads to different fluorescence spectra. Moreover, the high-resolution emission spectra of CDMA become severely congested upon exciting higher energy transitions, e.g., 0,0 + 632 cm^{−1}, 0,0 + 916 cm^{−1} and 0,0 + 1158 cm^{−1}. To explain these findings, the hypothesis that the fluorescence is preceded by a fast (i.e., on the picosecond time-scale) radiationless intramolecular process (probably internal conversion from the primary excited state to another excited electronic state of lower potential energy minimum) has been proposed [90c,d].

Figure 10. Experimental (a) and simulated (b, c) rotational band contours of the 0–0 +76.1 cm⁻¹ vibronic band of the LIF excitation spectrum of CDMA. The band contour (b) is based on *ab initio* geometries (the torsional angle between the donor and acceptor moieties is 22°). The band contour (c) assumes that the dimethylamino group is not twisted in the ground and excited states. Reproduced with permission from Ref. [92 b].

3.2.3 Microsolvation Effects

Electron donor–acceptor molecules linked by a single bond have been widely used for studying structural requirements and solvation effects upon photoinduced intramolecular charge transfer processes. Polarity, acidity and viscosity may all act to influence the relative accessibility and stability of the CT state and the kinetics of its population. Solvation may affect the barrier height, the well depth and the electron transfer probability. Molecular aspects of solvation can be studied by the investigation of isolated gas phase solute–solvent clusters, which are formed in a supersonic jet expansion. Among the issues concerning the excited-state CT process are (i) critical number of solvent partners of the defined polarity; (ii) relative contributions of the local and the long-range stabilizing forces and (iii) details of the solute–solvent interactions, e.g., steric effects, solvation site(s), solvent orientation and hydrogen bonding.

Experiments with clusters in a supersonic jet can advantageously be employed to study the effects of solvation of a chromophore on its emission spectrum. Hence it is desirable to characterize the composition and the structure of the solute–solvent clusters as precisely as possible. The cluster size distributions can be determined by TOF-MS after resonant two-photon ionization, R2PI [84, 92a,c]. This allows for a

better characterization of the cluster sizes in the emission experiments than correlation with expansion parameters such as sample temperature and the stagnation pressure of the carrier gas (e.g., [82, 83, 85–91, 93–95]). The former method presumes that fragmentation induced by the ionization is negligible, which is generally not the case. However, with the use of very low laser intensities and of ionization energies very near to the ionization threshold, one can correlate the species contributing to the fluorescence spectra with the cluster ion mass spectra. To avoid falsification of the mass spectra by fragmentation of larger clusters, the intensity dependence of an ion mass signal on laser power and excitation wavelength should be tested. The cluster size distribution can be varied by changing the sample/nozzle temperature and by adjusting the time delay between the laser pulse and the opening pulse of the valve.

Homogeneous aggregates

The dimers of 4-(dialkylamino)pyrimidines (**VI–IX**), show structured LIF excitation spectra (an example is shown in Figure 11) [90a–c]. The origin is shifted to the red with respect to that of the bare molecule by about $600\text{--}700\text{ cm}^{-1}$ (Table 2). The dispersed fluorescence spectra of the dimers are surprisingly narrow and the spectral position of its maximum (centered at about $330\text{--}335\text{ nm}$) is similar to that of the bare molecule. It is plausible to assume for these dimers a nearly planar geometry with a head-to-tail conformation stabilized by a hydrogen bond between the dialkylamino hydrogen and the pyrimidine ring nitrogen atoms. It is noteworthy that for the nonplanar compounds **VIII** and **IX** two kinds of dimers are observed. The second type of dimers show structureless excitation spectra and their fluorescence is markedly red shifted (the maximum is centered at about 400 nm). This finding suggests the transformation of these ground-state van der Waals (vdW) complexes into excimers (see below).

The LIF excitation spectrum of the dimers of jet-cooled CDMA is structureless and the low-energy part is red shifted by about 1500 cm^{-1} with respect to the $0,0$ transition of the monomer [84b]. The emission spectra for a homogeneous expansion of **I** in helium depend strongly on the size of excited clusters. The dimers show significantly broader and red-shifted fluorescence with respect to that of the monomer. The emission maximum is centered at 390 nm [82c,d, 83, 92a]. Formation of larger clusters ($n \geq 3$) shifts this maximum to 410 nm [92a]. Similarly, the structureless excitation spectra and the red-shifted emission spectra centered at 405 and 400 nm are observed for the dimers of **II** and EIN (the latter does not show dual luminescence phenomenon in solutions), respectively. On the other hand, the formation of clusters does not change markedly the position of the fluorescence maximum of the monomers of CTMA (however, the increase of the intensity of the long-wave part of the spectrum is observed). Luminescence properties of ABN clusters differ from those observed for CDMA and its other derivatives. Under expansion conditions where only small clusters ($n \leq 3$) are observed in the TOF ion mass spectrum, an additional long-wave band is not observed in the fluorescence spectrum (Figure 12). The appearance of larger aggregates results in a red-shifted emission with a maximum centered at 395 nm [92a].

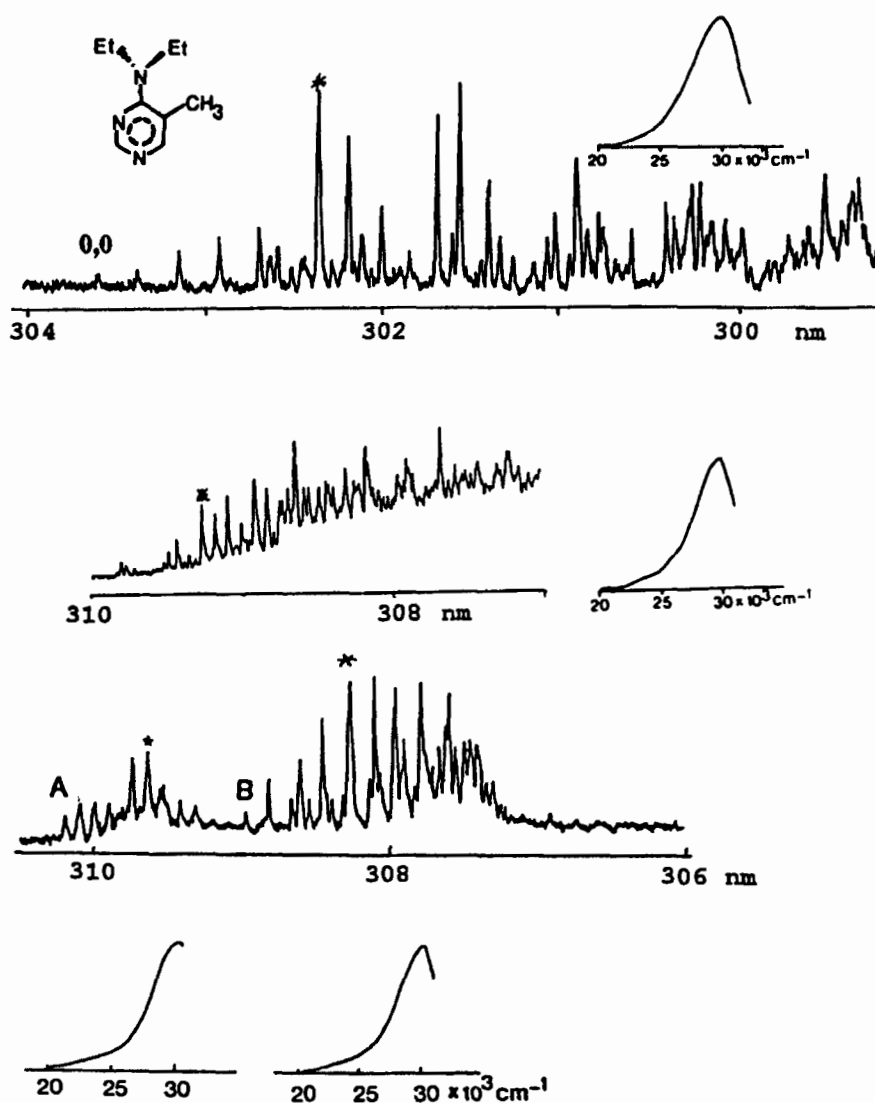

Figure 11. LIF excitation and emission spectra of jet-cooled monomer and clusters of IX [90a–c]: top, monomer; middle, dimer; bottom, van der Waals complexes between IX and acetonitrile. The electronic origins of the excitation spectra of the latter complexes are labelled A (1:2 complex) and B (1:1). Low-intensity features of the 1:3 complex are observed in the red part of the spectrum with the high pressure of acetonitrile. The fluorescence spectra were recorded with a spectral resolution of the detection monochromator of 10–15 nm (the position of excitation is indicated by an asterisk).

Table 2. Electronic origin (in nm) of the excitation spectra (as obtained from the LIF spectroscopy and REMPI-TOF-MS) of 4-dialkylamino derivatives of benzonitrile (**I**, **II**, **IV**)^a and pyrimidine (**VI–IX**), methyl 4-dimethylaminobenzoate (**XI**) and their clusters with various polar solvent molecules [the displacement in cm⁻¹ (- denotes the red shift and + the blue shift) of the 0,0 transitions of the clusters with respect to the monomer origin are included]

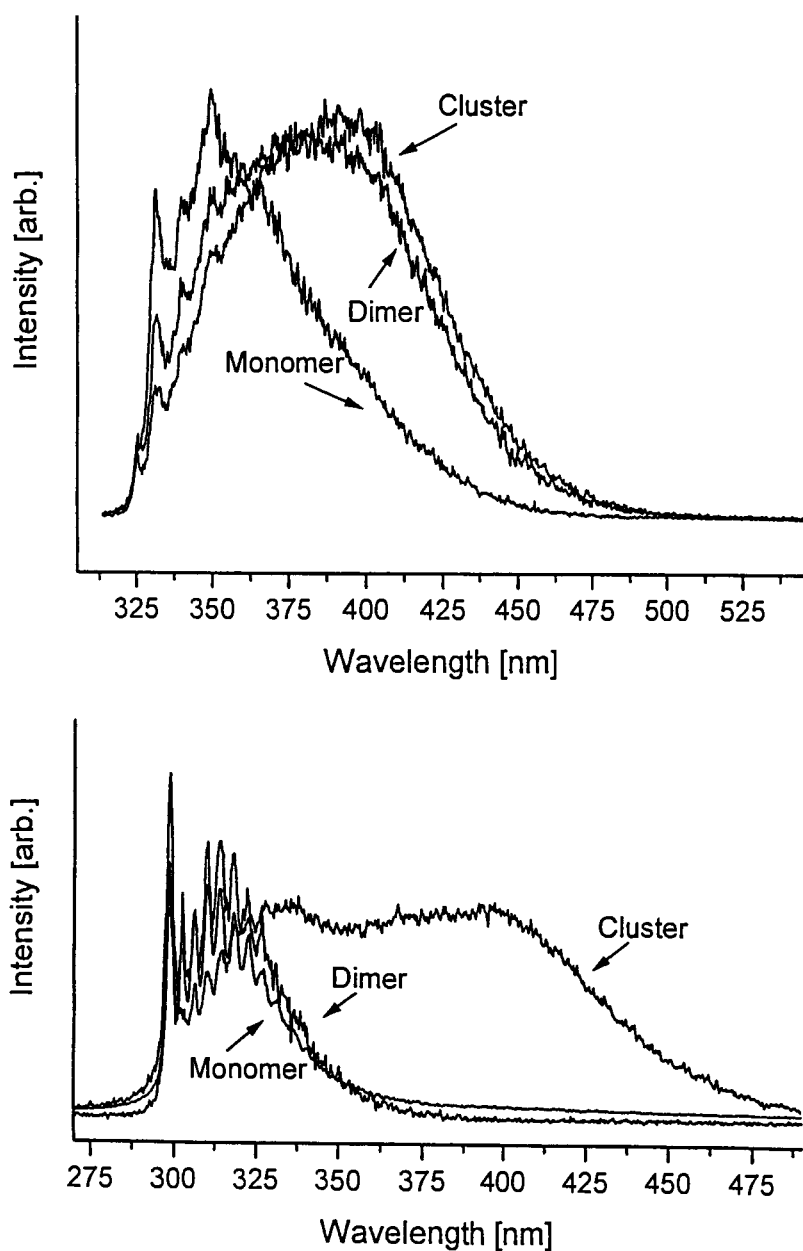

Figure 12. Dispersed emission spectra of jet-cooled monomer, dimer and larger homoaggregates upon 0,0 excitation: top, E1N; bottom, ABN. Reproduced with permission from Ref. [92a].

The changes in the emission spectra of DMAEB resulting from the cluster formation in the supersonic beam are presented in Figure 13 [92a]. The long-wave emission band (which is centered at 410 nm) was previously observed by Phillips and co-workers [82c, 93] and attributed to dimers, owing to its concentration dependence. Similar spectra have been observed for monomers and dimers of DMAMB [91, 93, 94]. The LIF excitation spectra of the dimers of both molecules are structureless and extend far to the red (about 1800 cm^{-1}) with respect to the monomer 0,0 transition.

Correlation between the mass and emission spectra demonstrates that the observed long-wave emission in all the compounds under consideration is due to the formation of self-complexes. The origin of this band has been a subject of intense discussion. Following the arguments given by Phillips and co-workers [82c,d] the red-shifted fluorescence of the CDMA dimer can be due to its transformation into an excimer or the transition into an intramolecular ^1CT state (e.g., TICT state) of one chromophore is induced by its polar partner. There is no doubt that detailed characterization of the conformational reaction coordinate is crucial for understanding of the mechanism of the excited-state process, an extremely difficult task for jet studies of transitions terminating on a repulsive ground-state potential energy surface(s) at the geometry of the relaxed excited state (cf. Figure 18). Some help, however, comes from comparative studies of the investigated compounds. The occurrence of the long-wave fluorescence for dimers of EIN and for larger than trimeric homoaggregates of ABN suggests that this band is not due to the TICT state formation (neither ABN nor EIN show dual fluorescence in solutions). It has been proposed by Lommatzsch et al. [92a] that the absence of dual fluorescence for the ABN dimer is due to a planar head-to-tail conformation (stabilized by a hydrogen bond between the amino hydrogen and the nitrogen of the cyano group) which prevents the formation of excimers. For the same reasons, a cyclic structure for the trimer has been proposed. The comparison of the effects of dimer formation of CDMA and benzoic acid esters (**XI** [93, 94], **XII**) on the emission spectra strongly suggests the transformation of the ground-state vdW complexes into excimers. In the vdW dimer two partners (M) are identical. The excimer state is stabilized by configuration interaction with charge resonance states ($M^-M^+ \leftrightarrow M^+M^-$) and exciton resonance states ($M^*M \leftrightarrow MM^*$) [28a, 37b, 60a]. The stabilization of an excimer due to charge resonance is given by the potential energy function:

$$V = IP - EA - C(r) \quad (11)$$

where IP is the ionization potential, EA is the electron affinity of the monomer subunit and $C(r)$ is the Coulomb attraction. When both molecules are in a suitably arranged contact, an exciton interaction can mix the two S_1 states of the monomers and split them by equal amount of energy $\pm \Delta E_{\text{exc}}$. The corresponding potential energy function in the dipole–dipole approximation can be obtained from the relation

$$V = E_M \pm \Delta E_{\text{exc}} = E_M \pm \frac{\vec{M}_1 \vec{M}_2}{r^3} \quad (12)$$

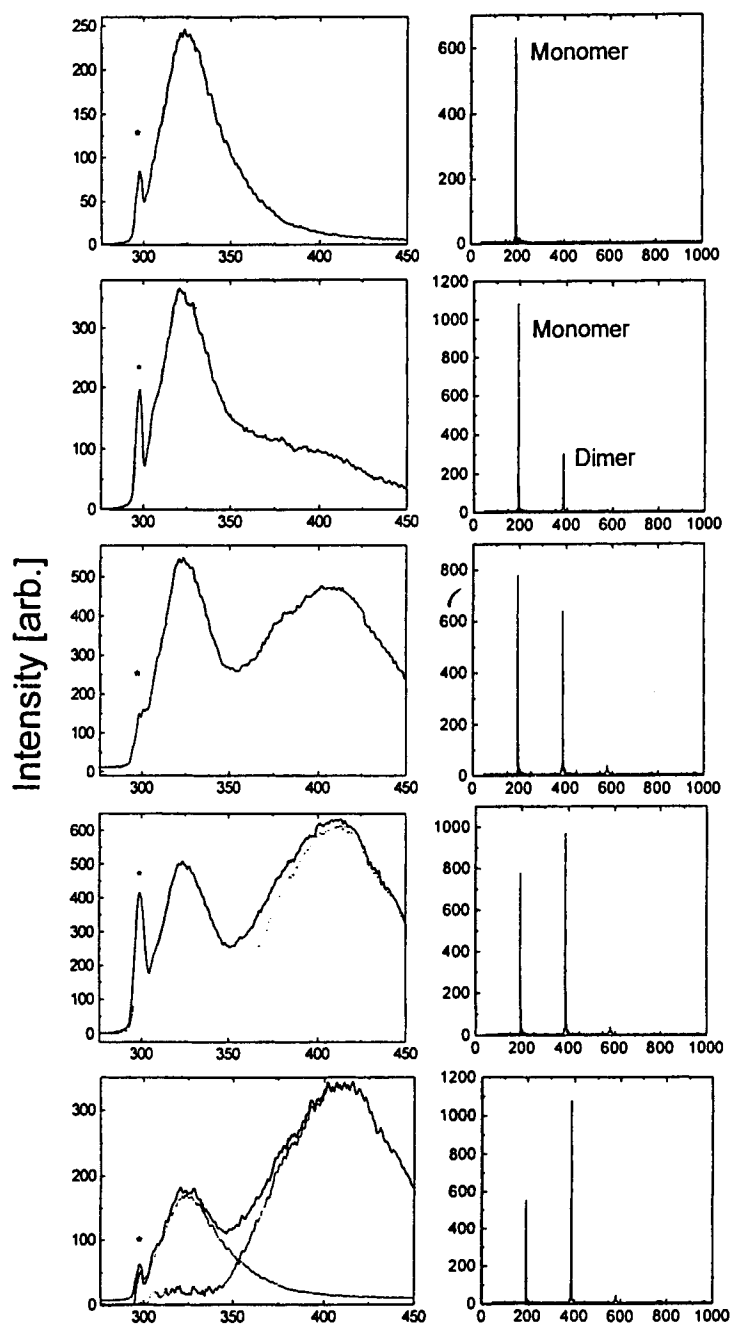

Figure 13. Left, dispersed emission spectra (recorded with a low resolution of the detection part) of jet-cooled monomer and self-clusters of DMAEB (XII). Right, time-of-flight mass spectra. The cluster size distribution was varied by changing the operating conditions of the pulsed nozzle. Reproduced with permission from Ref. [92a].

where \vec{M}_i ($i = 1, 2$) is the transition dipole moment, E_M is the unperturbed energy of the monomer excited state and r is the intermolecular distance between the monomer moieties in the excimer. Thus, the exciton interaction of the 1L_a states results in the larger stabilization of the excimer than that connected with the interaction of the 1L_b states. The magnitude and sign of ΔE_{exc} depend on the mutual orientation of both partners. The favorable geometry of the vdW dimer for singlet excimer formation is a sandwich-like conformation. When the transition dipole moments are parallel the exciton interaction is strong and when they are perpendicular the interaction vanishes. In the case of the ideal sandwich geometry, the out-of-phase combination ($-$) of the (M^*M) and (MM^*) wavefunctions is the lower exciton state, whereas for an in-plane head-to-tail orientation, the in-phase combination ($+$) is the lower exciton state. To estimate the stabilization of the CDMA excimer due to exciton resonance interactions, both the 1L_b and 1L_a states have to be considered [28a, 92a] (see the schematic diagram in Figure 14). The excimer of CDMA is expected to be stabilized about 0.28 eV below the 1L_b state of the monomer. The exciton stabilization effects in benzoic acid esters (**XI**, **XII**) should lead to a larger red shift of the emission spectra (even if the sequence of the 1L_b and 1L_a states in DMAMB and DMAEB is the same as in CDMA the energy gap is expected to be much smaller [23, 85, 91, 94]), and this is observed.

Figure 14. Schematic diagram of the stabilization of the CDMA excimer due to exciton resonance interaction. An ideal sandwich-like conformation with opposite orientation of the two monomers is assumed for the excimer. The values of the excited-state energies and the corresponding transition dipole moments were taken from Ref. [33c]. The exciton splitting of the 1L_b state is only 39 cm^{-1} , owing to the low transition dipole moment M_{lu} corresponding to the $^1L_b \leftarrow S_0$ emission. The much larger M_{lu} value for the $^1L_a \leftarrow S_0$ fluorescence makes the exciton splitting of the 1L_a state the dominant stabilization. The in-phase and the out-of-phase combinations of the exciton resonance states are labeled L^+ and L^- , respectively. The unknown contributions of the charge resonance interaction are indicated by a question mark. Reproduced with permission from Ref. [92a].

Figure 15. Potential energy surface(s) for excimer formation. Reproduced with permission from Ref. [92a].

The excimer fluorescence (with respect to the excited vdW dimer emission) is red shifted and structureless because the emission is terminated in a repulsive ground-state potential energy surface (Figure 15). For parallel transition moments, emission from the out-of-phase exciton state to the ground state is forbidden and for the in-phase exciton state emission is allowed [28a]. It should be noted, however, that the forbidden emission from the out-of-phase exciton state is expected to have a similar transition dipole moment as the $^1L_b \rightarrow S_0$ emission. The actual dynamics of the initially excited vdW dimer depend on the energy gap and the coupling strength between the primary excited (LE) state and the excimer state.

Heterogeneous clusters

Specific effects on spectroscopy and photophysics induced by complexation of the D–A chromophores with various solvent molecules have been examined for all the compounds under consideration. The idea of the beam work is to generate 1:*n* solute–solvent complexes and to determine thereby the relation between the solute–solvent interactions and the excited-state CT process. Kajimoto et al. [81a,c, 89], Phillips and co-workers [82], Peng et al. [83], Bernstein and co-workers [84] and others [85, 88, 90–92] have shown that solute–solvent complexes of CDMA were readily produced by varying the partial pressure of the compounds and the stagnation pressure of the carrier gas. Cyclohexane, chloroform, carbon tetrachloride, methyl fluoride, trifluoromethane, dichloromethane, acetone, acetonitrile, metha-

nol, water, ammonia and dimethylamine have been used as solvents. Some of the complexes show structured excitation spectra (a few examples are collected in Table 2) and narrow short-wave LIF emission spectra (which strongly resemble the fluorescence spectra of the bare molecule). The fluorescence has been assigned to the primary excited state of the vdW complexes.

Similar results have been obtained for the complexes between benzoic acid esters (**XI**, **XII**) [88d, 91, 94] or 4-dialkylaminopyrimidines (**VI–IX**) [90, 92d] and polar and protic solvent molecules. The results in Table 2 show that polar partners induce a wide range of both bathochromic and hypsochromic shifts. The two most important interactions are dipole–dipole and hydrogen bonding, both of which are strong and directional in nature. Thus, the magnitude and direction of solvent shifts with polar solvents are very sensitive to the binding site and relative orientation of the solvent molecule. In many cases, several distinct isomers have been detected, with different solvent shifts for the same complex stoichiometry. For example, the excitation spectrum of **VII** complexed with methanol (Figure 16) exhibits four different regions, all of them giving rise to short-wave fluorescence [90a–c]. The spectral origin is either blue (**D**) or red shifted (**A**, **B** and **C**) with respect to that of the monomer (Table 1). TOF-MS experiments [92d] proved that the complexes **C** and **D** are of 1:1 and **B** and **A** of 1:2 and 1:3 stoichiometry, respectively (the 1C-R2PI-TOF mass spectra show a structure very similar to that observed by LIF spectroscopy). The LIF spectra of the complexes of **IX** with acetonitrile are presented in Figure 11. The LIF [90a–c] and 1C-R2PI-TOF-MS [92d] experiments indicate that the excitation spectrum corresponds to three complexes of different stoichiometry. The 0,0 transitions of these complexes are shifted to the red by 595 cm^{-1} (1:1 complex), 721 cm^{-1} (1:2) and 770 cm^{-1} (probably 1:3) with respect to the origin of the monomer. The vibrational structure of the excitation spectra of the complexes differs markedly from that of the bare molecule (the spectra show different Franck–Condon envelope and smaller frequency spacings between the vibronic bands). For these complexes the first vibronic band is fairly intense, which suggests that in the complexes the displacement of the equilibrium conformation is smaller than that in the bare molecule.

The effects of the mixed supersonic expansion of CDMA with various solvent molecules (such as cyclohexane, carbon tetrachloride, acetone, acetonitrile, methanol, dichloromethane and chloroform) on the emission spectra have been investigated by Phillips and co-workers [82d]. The cluster size distribution was varied by changing the nozzle temperature and the partial pressure of the solvent. Two emission components were observed in each case. The long-wave emission was attributed to dimers (which can be isolated or solvated) and to monomer complexed with chloroform or dichloromethane (of unknown stoichiometry). On the other hand, it has been reported by Bernstein and co-workers [84] that CDMA forms with acetonitrile two kinds of 1:1 complexes of different geometry. The first cluster has a structured excitation spectrum, similar to that of the bare molecule, but blue shifted by about 252 cm^{-1} . The second exhibits a broad excitation spectrum with some resolvable features between $31\,400$ and $31\,600\text{ cm}^{-1}$ (Table 2). The complexes show different fluorescence spectra; excitation into the broad absorption leads to the red-shifted emission with respect to that of the monomer (Figure 8) and of the ‘blue’

Figure 16. LIF excitation (scale in cm^{-1}) and emission (scale in nm) spectra of VII with methanol and water [90a–c]. The electronic origins of the LIF excitation spectra of various complexes are labeled A (complex of stoichiometry 1:3), B (1:2), C (1:1) and D (1:1). The spectra of the complexes with water do not show the low-energy parts A and B. The fluorescence spectra were recorded with a spectral resolution of the detection monochromator of 10–15 nm (the position of excitation is indicated by an asterisk).

cluster (with a maximum centered at about 345 nm). The effects of the gradual complexation of CDMA, ABN and EIN by acetonitrile, tetrahydrofuran (THF) and cyclohexane on the fluorescence spectra have been investigated by Lommatzsch et al. [92c] with the use of the experimental set-up that combines TOF-MS with dispersed emission spectroscopy (Figure 7). Two different (chromophore)_m–(solvent)_n cluster size distributions were studied: (i) complexes containing one chromophore molecule ($m = 1$) and a small number of solvent molecules ($n = 1–4$) and (ii) complexes of one chromophore and a large number of solvent molecules ($n = 1–12$). As discussed above in this Section, the homogeneous clusters of CDMA and its derivatives exhibit dual fluorescence, because of excimer formation [82c,d, 92a]. Therefore, to avoid interference of excimer emission with the emission from the heterogeneous clusters, the formation of homogeneous dimers should be suppressed. Figure 17 shows the emission spectra of ABN and EIN complexed with a small number of solvent molecules. For both chromophores an increasing red shift of the emission maximum with respect to the uncomplexed chromophore is observed with increasing polarity of the solvent partners. No significant changes of the emission are observed with increasing size of the ‘solvent shell’ (i.e. from $n \leq 4$ to $n \leq 12$). It is noteworthy, that the emission maxima of the complexed chromophores in the jet resemble closely those in the respective solutions. In particular, no second, anomalous and red-shifted emission band is found under these expansion conditions. CDMA–solvent clusters seem to show different behavior. Under the expansion conditions favoring the formation of monomers and clusters between CDMA and acetonitrile of 1:1 stoichiometry, the observed emission shows two maxima centered at 325 and 345 nm. The formation of 1: n clusters (with $n \geq 5$) gives rise to a strongly red-shifted and clearly separated second emission with a maximum centered at about 425 nm. The contributions of dimers and 2: n complexes were excluded by the correlation of the increase of the intensity of the long wavelength emission with the concentrations of various mass analyzed ionic clusters [92c]. The effects of the gradual complexation of CDMA by methanol and THF on the luminescence are qualitatively very similar, but dispersed fluorescence spectra show different shape and spectral position of the long-wavelength band. This finding agrees with previous results for the jet-cooled 1:1 complexes between CDMA (**I**) and water [81a, 83], methanol [82a, 83], acetonitrile or ammonia [83] which showed that one polar solvent molecule is definitively not enough to observe this emission. It is noteworthy that this result for CDMA is different from the behavior of methyl 4-dimethylaminobenzoate (**XI**) where the long-wave fluorescence has been reported for 1:1 complexes with water [91].

Hence the detailed investigations demonstrate that the luminescence properties of the heterogeneous clusters of ABN and EIN differ from those of **I** and **XI**. Whereas for the clusters of the two former compounds with polar solvent molecules only one emission band appears (being red shifted with respect to the monomer), those of **I** [probably of 1: n ($n \geq 5$) stoichiometry] and **XI** with water (of 1:1 stoichiometry) show dual fluorescence. This finding may be discussed in terms of a qualitative model presented in Figure 18. In general, the equilibrium conformation of a vdW cluster and the shape of the potential energy curves in the ground and primary excited state are usually different owing to a larger binding energy in the excited state

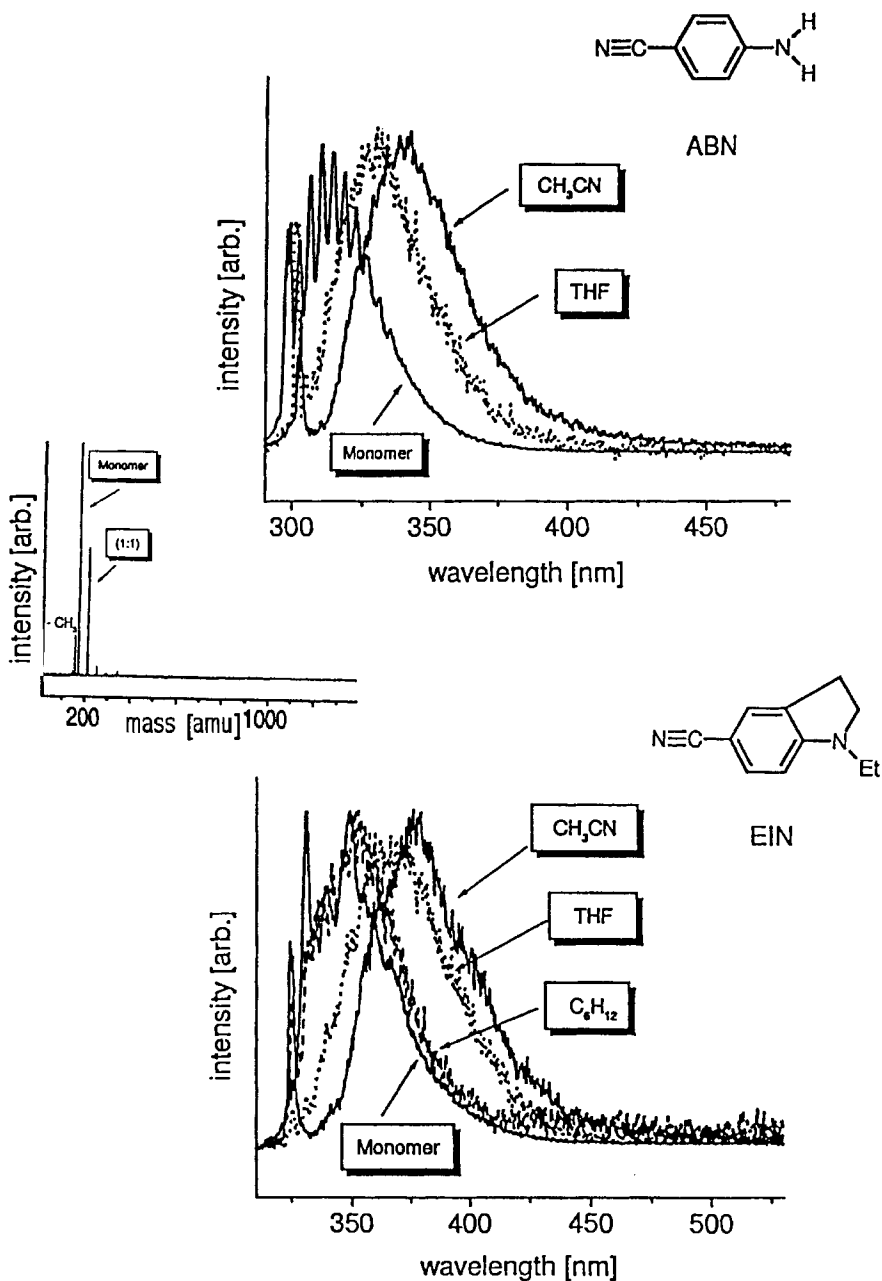

Figure 17. Dispersed fluorescence spectra of ABN (top, excitation wavelength 300 nm) and EIN (bottom, excitation wavelength 325.60 nm) and their complexes with a small number ($n = 1-4$) of solvent molecules such as cyclohexane (C₆H₁₂), tetrahydrofuran (THF) and acetonitrile (CH₃CN). The 1C-R2PI-TOF mass spectrum of EIN + CH₃CN expansion is also shown (middle).

Figure 18. Schematic representation of the potential energy surfaces of the ground and excited states along the reaction coordinate corresponding to the transformation of the vdW clusters (in the ground state represented by a shallow potential energy minimum) into excimers, exciplexes or intramolecular charge-transfer (ICT) states. These systems possess a double minimum potential in the resultant adiabatic excited state; the relative energy of the minima, the barrier height and the well depth is dependent on the electronic structure of the chromophore and the interactions with solvent molecules. (b) The barrier is high enough to prevent formation of excimers, exciplexes or ICT states. This is the case of the clusters that show structured excitation spectra and a short-wave emission from the primary excited state of the vdW complex. (a) The case with the clusters that are 'prepared' for the excited-state reaction. The diffuse excitation spectra are most likely due to the short lifetime of the primary excited vibronic levels of the vdW cluster which leads to the broadening of the individual lines. The difference between the geometry of the product of the excited-state reaction with respect to that of the ground-state vdW cluster generates a broad, red-shifted emission. The reaction coordinate of the excited-state reaction is complex, e.g., should be related to the intermolecular distance and the mutual orientation of the complexing partners combined with the intramolecular motions in the D-A chromophore such as torsion and inversion.

with respect to the ground state. This could result from the increase in the dipole moment and/or the polarizability of the D–A molecule, from exciton or CT interactions and/or from the interactions with the solvent molecules. The actual dynamics of a particular, electronically excited vdW complex depend on the electronic structure of the chromophore (e.g., the energy gap between the interacting electronic states) and on the intracluster interactions (which may depend strongly on the electron donor–acceptor properties of the solute and the equilibrium geometry of the solute–solvent clusters). It is most likely that the relatively small red shift of the emission of jet-cooled clusters between ABN and EIN and polar partners compared with that of the monomers and clusters with nonpolar molecules is caused by the change of the potential energy surface together with intramolecular vibrational redistribution, IVR (by the latter, various low-frequency vibronic states in the S_1 state can be populated). The striking appearance of dual luminescence in jet-cooled CDMA and DMAMB clusters with polar molecules must be of different origin. Following the arguments given by Bixon and Jortner [103c,d], Phillips and co-workers [82], Wersink and Wallace [94] and Yip and Levy [72b], the origin of a long-wave emission band can be due to the transformation of the vdW cluster into an exciplex (1: n complexes), a solvated excimer (2: n complexes) or the transition into an intramolecular CT state of the D–A chromophore which is induced by its polar partner. Most probably, the latter mechanism is responsible for the red-shifted emission of 1: n solute–solvent complexes. Its appearance is probably related to the lower ionization potential of **I** (and **XI**) compared with ABN, with energy difference amounting to at least 0.6 eV [121]. This value may be even larger in the case of the TICT state formation owing to the decoupling of the amino group. Thus, the relatively strong interactions between the primary excited state (S_1) and CT state (S_2) due to the small energy gap (Eq. 11, Ref. [122]) are expected for **I** and **XI**. The exclusion of an exciplex mechanism is suggested by the relatively low electron affinity and high ionization potential of the solvent molecules. However, it should be noted that larger subclusters of solvent molecules show a decreasing ionization potential [70b] and an increased electron affinity [123] in comparison with the monomer.

A critical evaluation of the findings described here needs some further remarks. As already mentioned, the determination of the cluster size distribution in the beam by R2PI-TOF-MS is limited by the intermolecular fragmentation of the vdW clusters in the ionic and, possibly, also in the fluorescent state. Clusters between aromatic chromophores and water, methanol and other polar molecules usually dissociate upon 1C-R2PI by losing one solvent molecule [124]. This fragmentation is mostly due to an excess energy in the ion after a non-resonant ionization transition and/or by a rearrangement of the ionized cluster due to the charge–dipole interaction. In addition to the fragmentation after ionization, an unknown amount of fragmentation could occur in the electronically excited state due to an exothermic process from the primary excited state of a vdW cluster to a CT state (Figure 18a). The system transforms a certain amount of electronic energy into vibrational energy which could be imparted by IVR to the solvent partners, followed by a fast predissociation of a vdW cluster. The dissipation of energy by fragmentation could be slowed with increasing number of coupled vibrational degrees of freedom (i.e.,

with increasing number of solvent molecules) in the vdW complex. Thus, in larger clusters under collision-free conditions IVR and internal conversion could be the dominant energy dissipation channels.

One of the methods which allows one to characterize the size and structure of the vdW complexes which are responsible for the specific photophysical properties is double resonance (IR/R2PI) laser depletion spectroscopy [70b]. This method combines the structurally sensitive infrared (IR) vibrational predissociation spectroscopy (VPS) with the highly mass-selective R2PI-TOF-MS. The VPS of clusters, pioneered by Gough and co-workers [125] and by Vernon and co-workers [126], has been described theoretically by Beswick and Jortner [127]. The IR/R2PI technique was subsequently applied to the study of jet-cooled molecular clusters by several groups [124, 128–130]. In such a pump and probe experiment, the cluster beam is irradiated by a pulsed, tunable IR laser. The absorption of IR photons matching a particular intramolecular vibration of a molecular subunit within the vdW complex leads to its predissociation. This depletion of selected complexes can be probed with a certain delay time (e.g., of about 100 ns) by R2PI-MS. Centering the UV probe laser on a size-specific band of a product ion while tuning the wavelength of the IR laser leads to an ion depletion spectrum corresponding to the IR absorption of the probed cluster in its neutral state. The comparison of the experimental spectrum with quantum chemical *ab initio* calculations gives information about the structure of the clusters. Moreover, the IR/R2PI method allows one to obtain the hole-burning spectra. The latter are recorded by keeping the wavelength of the IR laser fixed on a particular intramolecular vibrational transition while tuning the wavelength of the UV probe laser. The respective IR/R2PI spectrum differs from the normal R2PI spectrum (i.e., the excitation spectrum of a neutral complex observed via measurement of the ion yield as a function of the scanning wavelength of the UV laser) because of the depletion of all the bands corresponding to the clusters containing a particular IR absorber. With this method the spectroscopic features in an R2PI spectrum originating from fragmenting larger clusters, isomers or hot bands can clearly be identified and often assigned. It should be pointed out that this IR/R2PI hole-burning spectroscopy offers a unique chance to determine a cluster-specific fluorescence within a broad cluster size distribution. It can be done by comparing the LIF emission spectra recorded with and without the IR predissociation laser matching a particular intramolecular vibration. For example, if the difference emission spectrum contains an anomalous long-wave component, the formation of the excited CT state in this specific cluster can be determined unequivocally.

3.2.4 Concluding Remarks

Under jet-cooled conditions, no long-wave emission is observed for a series of the D–A compounds that show dual luminescence in solutions, except **III** (Figure 2). The observed broad emission (Figure 8) of the latter, highly ‘pretwisted’, molecule is a manifestation of the overlap of two fluorescences, **a** and **b** (Figure 3). The long-wave emission **a** dominates upon direct excitation to the ¹CT state and the intensity

of the short-wave emission **b** [corresponding to the $S_2(^1\pi, \pi^*) \rightarrow S_0$ transition] increases with excess excitation energy. High-resolution spectral investigations and quantum chemical studies provide a method for the elucidation of geometries in the ground and excited states.

Solute–solvent complexes of different stoichiometry have been observed between all the D–A compounds under consideration and various solvent molecules. Some of the clusters show structured excitation spectra and a narrow short-wave emission that has been assigned to the primary excited state of the vdW complex. The broad, red-shifted emission of other clusters can be explained in terms of the transformation of the vdW complexes of stoichiometry $2:n$ ($n \geq 0$) into excimers or the transition into an intramolecular CT state of the D–A chromophore which is induced by its polar partner(s) (for the complexes of stoichiometry $1:n$). The main conclusion from the fluorescence behaviour of the jet-cooled vdW clusters is that dual luminescence is obviously connected with the preference of specific solute–solvent geometries.

As has been discussed above, molecular clusters produced in a supersonic expansion are preferred model systems to study solvation-mediated photoreactions from a molecular point of view. Under such conditions, intramolecular electron transfer reactions in D–A molecules, traditionally observed in solutions, are amenable to a detailed spectroscopic study. One should note, however, the difference between the possible energy dissipation processes in jet-cooled clusters and in solution. Since molecular clusters are produced in the gas phase under collision-free conditions, they are free of perturbations from many-body interactions or macromolecular structures inherent for molecules in the condensed phase. In addition, they are frozen out in their minimum energy conformations which may differ from those relevant at room temperature. Another important aspect of the condensed phase is its role as a heat bath. Thus, excess energy in a molecule may be dissipated to the bulk on a picosecond time-scale. On the other hand, in a cluster excess energy may only be dissipated to a restricted number of oscillators and the cluster may fragment by losing solvent molecules.

A peculiarity of the cluster beams discussed above which has to be taken into account in the luminescence studies of intramolecular electron transfer processes is that even under beam conditions optimized for the production of small D–A solute–solvent complexes, the simultaneous appearance of homogeneous clusters is nearly inevitable. Hence excimer fluorescence and the fluorescence of the mixed clusters are often superimposed. Therefore, only the careful characterization of the clusters with respect to their constitution, size and structure can allow the unequivocal assignment of the processes observed.

3.3 Summary and Perspectives

The advent of supersonic molecular beam expansion techniques and high spectral- and time-resolved laser spectroscopic probing has transformed experimental

molecular spectroscopy, photophysics and photochemistry (e.g., [67, 70, 131]). Jet expansion of organic molecules allows the stabilization of both intramolecular conformers and intermolecular clusters. Analysis of their vibrational pattern and rotational band contours can provide detailed insights into their structures and their state-selective photophysics and photochemistry. Studies of molecular aspects of solvation of large jet-cooled organic chromophores lie at the intersection of many important types of research. The chromophore can be used to address questions of site selectivity (in polyfunctional molecules), the topography of intermolecular potentials and fundamental aspects of molecular recognition. LIF (or ionization) probing of jet-cooled clusters can be used to reveal both structural and dynamical information.

The recent development of tunable, ultraviolet, high-resolution dye lasers has opened up a new region of the spectrum to high-resolution studies [132]. For example, using such techniques combined with quantum chemical calculations, Kaya and co-workers [132e] determined the geometric structure of various jet-cooled complexes between 7-azaindole and water of 1: n ($n = 1-3$) stoichiometry. Femtochemistry, pioneered by Zewail [131], fulfilled the chemists' dream of being able to study the dynamics of chemical reactions in real time. For example, femtosecond molecular dynamics of phototautomerization in jet-cooled model DNA base pairs (7-azaindole dimers) containing two hydrogen bonds has been studied [133]. The stepwise (versus concerted) mechanism has been proved by using the phenomenon of Coulomb explosion of the reaction complex (caused by an intense femtosecond probe laser pulse) to arrest and interrogate directly the intermediates (by TOF-MS) in the latter reaction [134].

Clusters are (in spite of limitations and differences with respect to the condensed phase) adequate model systems to investigate the molecular roots of various processes with cluster-specific spectroscopic methods. The use of double resonance IR/R2PI laser depletion spectroscopy will probably have a great impact on future studies of the charge-transfer processes in mixed solute-solvent complexes. Other experimental methods that can be proposed for this kind of study are cluster-specific static and transient photoelectron spectroscopy (PES). In the latter case two synchronized, wavelength-tunable picosecond lasers are used, both for the excitation and the ionizing steps of R2PI. From the photoelectron spectra sampled at different delays of the ionization relative to the exciting laser, the CT dynamics may be investigated in real time. From the transient photoelectron spectra also the site of the charge separation may presumably be deduced. For example, after an intramolecular CT process in microsolvated CDMA the photoelectron spectrum should resemble that of the solvated benzonitrile anion, while a charge transfer to or from the solvent molecule (i.e., exciplex mechanism) should contain the signature of the solvent cluster ion.

Acknowledgments

We thank Professors Zbigniew R. Grabowski, Andrzej Kapturkiewicz, R.P.H. Rettschnick and Wolfgang Rettig and Dr. Uwe Lommatzsch for cooperation and

illuminating discussions. J.H. is grateful to the Polish Committee of Scientific Research, the Netherlands Organization for Scientific Research (NWO) and the Deutsche Forschungsgemeinschaft for generous support.

4 Exciplexes of Large Molecules

Yehuda Haas

4.1 Introduction

In this chapter we discuss electron transfer between closed-shell donors and acceptors. Important oxidation–reduction reactions of free radicals, such as take place in the gas-phase combustion of hydrocarbons, are excluded. We also shall not discuss systems in which an electron is transferred in the ground state. The only interaction assumed for the ground state is due to weak van der Waals forces. Under ambient gas-phase conditions, these forces cannot support a lasting bond between the two partners. In solution, these forces are of the same magnitude as solute–solvent interactions, and the large concentration excess of the solvent results in effective separation between the two. In the gas phase, thermal energies are of the same order as the binding energy, so that, on average, a very small fraction of these molecules are close enough for electron transfer to take place.

Electronic excitation can change, in principle, the nature of the interaction. A bound charge-transfer state is often found at excitation energies of 2–4 eV. Its origin has been discussed in several chapters in this series (see Volume I). The ionization energy of a molecular electron donor to be considered in this chapter is typically 8–10 eV. The electron affinity of the acceptor is of the order of 0.5–1.5 eV, so that at infinite separation charge transfer from the neutral pair requires a 7–9 eV photon—the far-UV region. Strong Coulomb attraction between the opposite charges leads to reduction of the total energy as the two charged components approach each other. The distance between the two components cannot become very small, as it is limited by Pauli repulsion forces between the electron clouds of the two partners as they come nearer to each other. The balance between the attractive and repulsive forces determines the distance between the two components at the minimum (equilibrium) energy of the ion pair. The Coulomb interaction at the equilibrium geometry of the ion pair (~ 3 Å) is about 3–5 eV, and the minimum is often found to be between 2.5 and 5 eV, an easily accessible range with available light sources.

In the bulk, the low concentration of ground-state pairs excludes their observation by absorption. The formation of the excited-state complex, termed exciplex, is a collisional process: electronic excitation of either the acceptor or the donor leads to the formation of a locally excited state (for instance, in hydrocarbon molecules, it is a $\pi\pi^*$ state). During the lifetime of this state, a collision with the other partner (which is in the ground state) leads to the formation of the exciplex. This mechanism is compatible with the fact that the absorption and fluorescence *excitation* spectra of the system are identical with those obtained by superimposing the spectra of the individual components. At the same time, the fluorescence *emission* spectrum changes drastically—a broad band, red shifted with respect to the bare molecule's emission spectrum, appears. It is usually devoid of vibrational structure, and is shifted to longer wavelengths as the solvent polarity increases [1].

The wavefunctions of these systems have been traditionally represented by superpositions of the wavefunctions of the separated systems plus those due to charge transfer: $\psi_g(\text{DA})$ is the ground state represented by the product of the wavefunctions of the separate components [$\psi_g(\text{DA}) = \psi_g(\text{D})\psi_g(\text{A})$]. Likewise, $\psi_1(\text{DA}^*) = \psi_g(\text{D})\psi(\text{A}^*)$, and $\psi_{\text{CT}}(\text{D}^+\text{A}^-) = \psi(\text{D}^+)\psi(\text{A}^-)$. In a simple model, these three states combine to form three diabatic states: the ground state, Ψ_G , a locally excited state, Ψ_{LE} , and an exciplex, Ψ_{Exc} :

$$\Psi_G = a_0\psi_g(\text{DA}) + a_1\psi_1(\text{DA}^*) + a_{\text{CT}}\psi_{\text{CT}}(\text{D}^+\text{A}^-) \quad (1)$$

$$\Psi_{\text{LE}} = b_0\psi_g(\text{DA}) + b_1\psi_1(\text{DA}^*) + b_{\text{CT}}\psi_{\text{CT}}(\text{D}^+\text{A}^-) \quad (2)$$

$$\Psi_{\text{Exc}} = c_0\psi_g(\text{DA}) + c_1\psi_1(\text{DA}^*) + c_{\text{CT}}\psi_{\text{CT}}(\text{D}^+\text{A}^-) \quad (3)$$

(In principle, other charge-transfer states, such as due to the D^-A^+ pair, as well as other locally excited states, such as the D^*A pair, should be included. Their contribution, however, usually turns out to be less important).

In the ground state, one finds that $a_0 \gg a_1$, $a_0 \gg a_{\text{CT}}$, in the locally excited state, $b_1 \gg b_0$, $b_1 \gg b_{\text{CT}}$, and in the CT (exciplex) state, $c_{\text{CT}} \gg c_0$, $c_{\text{CT}} \gg c_1$. The $\psi(\text{DA}^*)$ state is referred to as a locally excited state, since its character is basically that of an electronically excited acceptor molecule, A, van der Waals bound to the ground state donor, D.

As mentioned in the Introductory Chapter of this Part, jet cooling allows the easy synthesis of van der Waals (vdW) adducts between two molecules. This technique has been widely used by microwave spectroscopists to elucidate the structure and binding characteristics of loose vdW complexes [2]. Temperatures of the order of 1–10 K are easily achieved, so that the binding energy of the complex is much larger than the average thermal energy. A potential electron donor and acceptor may therefore be brought together to a short distance in their ground state, possibly facilitating electron transfer if proper energetic conditions are met. The energy required for the electron transfer is provided by a photon, but after photoexcitation, the system may undergo several competing processes in addition to electron transfer. One of the difficulties encountered in gas-phase systems is the fact that charge separation is not a favoured process, in the absence of the stabilizing effect of the solvent. Hence back electron transfer often dominates the overall yield of the process.

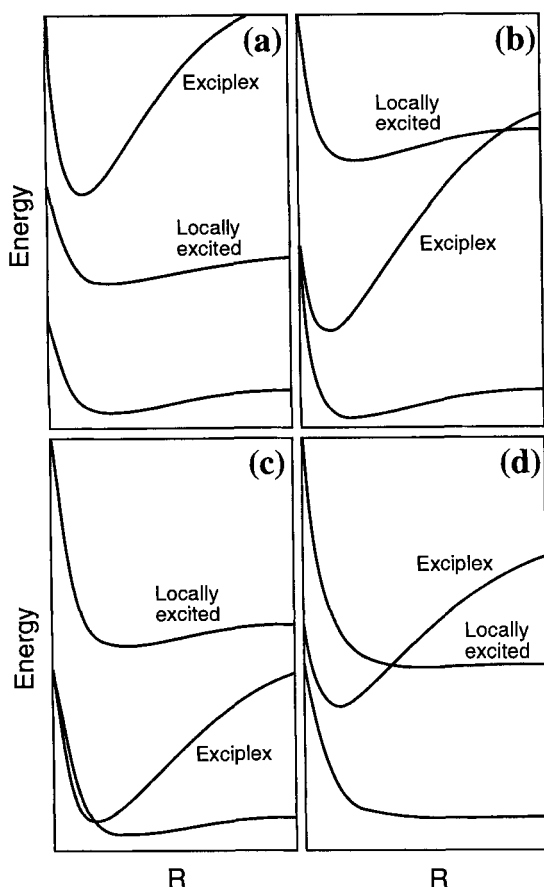

Figure 1. Schematic energy level diagram of exciplex systems. Adapted from Ref. [3]. See text for details.

Within the three-state model represented by Eqs. 1–3, the photophysics of potential exciplex systems are often discussed in terms of the simplified energy level diagrams shown in Figure 1 [3]. The two electronically excited states considered are the locally excited (LE) state, which in this chapter will be in general the first valence electronically excited state of the acceptor molecule, and an exciplex-type state, extrapolating at infinite distance to the separated ions. The diagrams are drawn along a single coordinate, R , the separation between the donor and the acceptor. This is a gross over-simplification for polyatomic systems. In fact, it is recognized that the system's energy depends on other coordinates, which may be most important for the understanding of the dynamics of electron transfer. In most cases, R is taken as the centre of mass separation, but sometimes the edge-to-edge distance is used.

Four schematic situations are shown in Figure 1. In (a), the exciplex state is at a much higher energy than the LE state at all intermolecular separations; excitation of the LE state cannot lead to electron transfer. It is noted that solvation may considerably reduce the energy of the exciplex state, so that the two energy curves may

cross in solution. In (b) the exciplex state is at a much lower energy than the LE state at about the equilibrium distance in the ground state. Franck–Condon excitation into the LE state is not likely to lead to charge separation, since the crossing of the two curves is near the dissociation energy of the LE state into A^* and D. In (c), the exciplex state is strongly stabilized, and mixes with the ground state. This situation leads to the formation of an ion-pair ground-state system, and the absorption spectrum of the system is characterized as a charge-transfer transition [4].

The situation depicted in (d) is the one most relevant to this chapter. Here, the crossing between the exciplex and the LE state is near the minimum of the latter. According to the Franck–Condon principle, absorption into the LE state is much favored over direct excitation of the exciplex. Nonetheless, excitation of the LE state creates a non-stationary state, which evolves in time. The transition between the two states is most likely to occur near the curve-crossing point. Therefore, analysis of these systems is in terms of radiationless transitions from the initially excited LE state to the exciplex state. Experimentally the latter is observed directly by its characteristic emission, or indirectly by its photochemical consequences. Inspection of the figure shows that the minimum of the exciplex state energy curve is at a smaller R than that of the ground-state van der Waals complex. Emission will therefore be strongly red shifted with respect to the excitation frequency. In addition, the emission is mostly to the repulsive part of the ground-state curve, so that the pair dissociates and the emission spectrum is broad and devoid of vibrational structure. These are the characteristic indications of exciplex-type emission.

The topic of electron transfer in jet-cooled systems has been reviewed several times in the past, in some cases with special attention to exciplex formation [3, 5]. These reviews covered the literature up to 1993 fairly extensively. We shall concentrate on the main advances made since that time, while giving an overview of the current understanding of these systems.

4.1.1 Evidence for Electron Transfer in Isolated Systems

When a potential acceptor molecule (such as anthracene) is cooled in a rare gas jet, its absorption and emission spectra are considerably simplified compared with the bulk: vibrational and even rotational bands are easily separated, and hot bands are eliminated, leading to removal of spectral congestion. Owing to the low number density characterizing supersonic jets (10^6 – 10^9 molecules cm^{-3}), absorption spectroscopy is rarely used in the UV range, and is replaced by more sensitive detection methods such as fluorescence or ionization. Thus, the fluorescence excitation spectrum or the ionization action spectra are frequently used. (In microwave [2] or high-resolution infrared spectroscopy [6], the very narrow bandwidth available allows the use of absorption spectroscopy in jet-cooled systems). The UV spectrum consists of a series of vibrational bands whose widths (for aromatic molecules) are of the order of 1 cm^{-1} , determined by the rotational envelope. The rotational structure of clusters can be analyzed by increasing the spectral resolution to 0.01 cm^{-1} and beyond. Fluorescence excitation has been used to record the rotationally resolved spectra of fairly large clusters such as argon and methane van der Waals complexes of naph-

thalene derivatives [7] and the cyanonaphthalene–trimethylamine complex [8]. The spectra allow the determination of the moments of inertia of the ground and excited states of these clusters, and hence the approximate determination of their structures. Mass-selected resonance-enhanced two-photon ionization was used to probe clusters of benzene and argon at a similar resolution [9]. These few examples (which are far from exhaustive) demonstrate the power of current spectroscopic instrumentation to provide very detailed information on the structure and energetics of van der Waals clusters in both the ground and excited electronic states.

Under lower resolution, the linewidths of the vibronic bands are of the same order as those of the bare molecule in both fluorescence excitation and emission. In some cases, the *emission* fluorescence spectrum is different, exhibiting broad emission bands. This situation is encountered when the co-seeded molecule is a potential electron donor, such as an aromatic or aliphatic amine. The jet spectrum in this case is very similar to solution spectra: it is broad (typical width $\sim 3000\text{ cm}^{-1}$), strongly red shifted from the excitation wavelength and is usually characterized by a long decay time. For instance, whereas the fluorescence lifetime of bare anthracene is about 20 ns in the jet, the anthracene–dimethylaniline adduct has a decay time of about 300 ns [10]. Based on a comparison with solution-phase studies, in which these spectra were identified as being due to the formation of an electronically excited charge-transfer complex, the broad emission spectra were assigned to an excited state having a strong charge-transfer character.

It should be noted that broad emission spectra are also observed in some cases for molecular dimers and larger aggregates, e.g., in the case of naphthalene [11]. The excited state in these homogeneous clusters is characterized as an excimer, and the interaction between the two components is mainly due to exchange interactions, although the contribution from charge-transfer states such as A^-A^+ is also important [12, 13].

Charge transfer can take place also when the acceptor and the donor are linked covalently by an ‘inert’ bridge. The bridge can be a flexible chain of CH_2 groups, a semi-flexible structure made, for instance, of cyclohexane or piperidine rings, or a rigid bridge of fused norbornane and bicyclo[2.2.0]hexane units. These bridges are considered to be inert in the sense that they act only to transmit the charge and not as charge sources or sinks. This topic is covered elsewhere in the chapter by Paddon-Row (Chapter III.2.1). Several excellent reviews are available; the most recent one by Wegewis and Verhoeven discusses extensively the jet work of the Amsterdam group [14].

When the bridge itself contains a potential electron donor or acceptor, the situation can be more complex. Thus, Tsujiya et al. [15] studied the intramolecular electronic interaction between anthracene (An) and dimethylaniline (DMA) in bridged systems, when the bridge contained an ethereal oxygen. In these systems it was found that the appearance of exciplex emission depended strongly on the relative position of the ethereal oxygen with respect to the anthracene part of the molecule. For 1-An-O-(CH_2)₂-DMA, one conformer was found to exhibit no exciplex emission at all in the jet, whereas another showed both locally excited and exciplex emission. For 1-An- CH_2 -O- CH_2 -DMA (and also for 9-An- CH_2 -O- CH_2 -DMA), no exciplex emission was found in the jet, although the same molecules show exciplex emission in solution! It appears that the interaction between

$\text{CH}_2\text{--O--CH}_2$ and anthracene is sufficiently strong in the jet to prevent population of the charge-transfer state. The mechanism of this interaction needs further clarification.

4.2 Structure–Reactivity Relationships

Early work (prior to 1990) concentrated on the gross features of jet-cooled exciplexes. In the absence of collisions, and at the very low temperature prevailing, it was hoped that it would be possible to find whether certain structures are more inclined than others to permit charge transfer in the excited state. It was soon realized from the pioneering work of Itoh's group on intermolecular clusters [16] and of Zewail's group on linked pairs [17] that in certain systems, excess energy is required in order to induce charge transfer. Changing the excitation wavelength varied the energy content of the system. In this case, the energy initially resides in the internal vibrational degrees of freedom of the acceptor, and has to be transferred to intermolecular degrees of freedom, to allow electron transfer. It was assumed that structural reorganization was necessary, for instance that the donor and acceptor moieties must achieve a certain relative alignment so that the necessary curve crossing can take place.

Levy and co-workers [18] studied a number of linked donor acceptor systems. The acceptor was anthracene and the donor an aniline derivative. The donor and acceptor were linked by a $(\text{CH}_2)_n$ chain with n varying between 1 and 4, the link to the aniline moiety being through the nitrogen atom [$9\text{-An}-(\text{CH}_2)_n\text{-N}(\text{CH}_3)\text{C}_6\text{H}_5$]. Only excitation near the origin was investigated—the goal was to find out whether the system could transfer an electron upon electronic excitation without adding excess vibrational energy. It was found that in the short-chain systems, only locally excited fluorescence was present. With $n = 4$, two different spectra were recorded, one exhibiting the narrow, well-resolved, vibrational structure of a locally excited state and the other showing a typical exciplex spectrum in both excitation and emission. The former was assigned to an all-*trans* conformer, in which the donor and acceptor are too far apart to allow electron transfer. In the latter, a folded conformation was assumed, based on a geometric calculation that showed that the donor and acceptor were at a van der Waals contact with each other. In this case it was argued that the charge-transfer state is lower in energy than the locally excited state, and that it interacts strongly with the ground state. In fact, the interaction is strong enough to impart a partial charge-transfer character to the ground state [4]. Under these conditions, the lowest lying electronic transition is of a charge-transfer character.

A similar situation is encountered in other systems. For instance, in the case of the pair pyrene (acceptor)–dimethylaniline (donor) connected by a propyl [$(\text{CH}_2)_3$] chain, one of the conformers is found to exhibit a charge-transfer band at the origin [19]. Another conformer, possibly a stretched one, shows only locally excited fluorescence at the origin, and exciplex type as the vibronic energy is increased. It seems that for strong acceptors, such as pyrene, an $n = 3$ chain is sufficiently long to allow

strong electrostatic interaction between the two components even in the ground state. Another example is the 1-(9,10-dicyanoanthryl)-3-(2-naphthyl)propane molecule, which exhibits a broad charge-transfer band in absorption. This is due to the fact that 9,10-dicyanoanthracene is a strong electron acceptor, allowing ground-state charge-transfer interaction with naphthalene when the two are connected with a propyl ($n = 3$) link.

In the early developments of this field, only energetic requirements were considered, and statistical methods were used to analyze the data [17]. The current effort is concentrated on a more detailed analysis, both experimentally and theoretically.

4.2.1 The Co-existence of Several Isomers

The very first fluorescence spectra of jet-cooled exciplexes indicated the existence of two types of ground-state van der Waals adducts. For instance, the anthracene–dimethylaniline system displayed two types of cluster bands in the fluorescence excitation spectrum: broad ($\sim 150\text{ cm}^{-1}$) and structureless, leading to typical exciplex emission, and narrow (1 cm^{-1}), leading to resonance-type emission [10, 20]. It was assumed that they are due to different 1:1 adducts, distinguished by different geometries. Recently, laser-based techniques were developed that allow the discrimination of different species. One is hole-burning spectroscopy and another—mass-selected photoionization.

4.2.2 Hole-burning Spectroscopy

In this method, two pulsed lasers are used, both usually in the nanosecond regime. One (the ‘burn’ laser) is operated at high power, and is scanned across the absorption spectrum. It excites molecules (or clusters) from the particular vibrational level (usually the $v = 0$ level) to an electronically excited state. The upper state relaxes (radiatively or otherwise) back to the ground state, but not necessarily to $v = 0$. Thus, depletion in the population of this species is achieved. A second, low-power laser (the ‘probe’ laser) is fired after a suitable time delay (to allow complete decay of the emission induced by the pump laser). It is tuned to one of the excitation spectrum vibronic bands of the system, and the fluorescence induced by it (the ‘signal’) is continuously monitored. Whenever the frequency of the burn laser corresponds to excitation of the species giving rise to the absorption of the probe laser, the signal is reduced. This reduction appears as a ‘hole’ that is burned in the spectrum—hence the name of the method. If a different species is excited (another molecule or a different vibrational level) no change in fluorescence intensity is incurred.

Itoh’s group and also Tramer, Piuze and their co-workers used this method extensively for the study of jet-cooled exciplexes. Examples of hole-burning spectra are shown in Figures 2 and 3.

The results of these studies may be summarized as follows. The first published application of hole burning to exciplex-forming systems in supersonic jets appears

Figure 2. Characterization of intermolecular exciplexes by hole-burning spectroscopy. Adapted from Ref. [22a]; (a) Fluorescence excitation ($\lambda_{\text{emission}}$ set at 375 nm) and (b) hole-burning spectra of the R-isomer of the anthracene–dimethylaniline (An–DMA) adduct in a supersonic jet. The probe laser was tuned on the most intense line of the adduct. Lines marked with asterisks are due to bare anthracene. (c) Fluorescence excitation ($\lambda_{\text{emission}}$ set at 450 nm) and (d) hole-burning spectra of the E-isomer of the An–DMA adduct in a supersonic jet. The probe laser was tuned to the maximum of the broad exciplex excitation band.

to be Piuze's 1993 paper [21]. A comprehensive summary of the group's results is given in two 1998 papers [22] and further information may be found in other papers [23, 24]. The acceptor in these systems was anthracene (An), and several aniline derivatives (see Scheme 1 for their structures) were used as donors. Early on, these

Figure 3. Example of fluorescence excitation and hole-burning spectra of an intramolecular exciplex: the fluorescence excitation spectrum ($\lambda_{\text{emission}}$ set at 395 nm, locally excited fluorescence) of 9-An-*m*-DMA (see Scheme 1 for structure) (b), along with two hole-burning spectra, (a) the probe laser set at $26\,644\text{ cm}^{-1}$ and (c) the probe laser set at $26\,689\text{ cm}^{-1}$. The arrows in (a) indicate the bands used for the probe lasers. Adapted from Ref. [19b].

workers [20], in agreement with other groups [10], showed that two different fluorescence spectra were observed in the jet-cooled An-DMA systems. These spectra were assigned to locally excited (LE) states, and to exciplex states. The former (termed R-isomers by Tramer and co-workers) were characterized by narrow-band systems in both emission and excitation. R stands for resonance, since the origin of these bands in excitation and emission coincided. The latter, termed E-isomers, showed broad and vibrationally unresolved emission spectra. E stands for exciplex; in this case, the structureless emission spectrum is strongly red shifted with respect to excitation. Mass-selective multiphoton ionization (MPI) showed that under appropriate expansion conditions, only 1:1 adducts were present in the jet expansion. The appearance of different excitation series in the fluorescence spectrum must therefore be assigned to isomers.

Hole-burning spectroscopy revealed one E-isomer and one to five R-isomers for each donor–acceptor pair. The E-isomer spectra, having broad bands, may in fact be due to several overlapping bands (see below). The spectra of the R-isomers, on the other hand, could be easily separated and analyzed. The number of isomers appears to depend on the complexity of the donor's structure: there is only one isomer for the parent molecule (DMA), and the largest number is found for DMOT (see scheme 1), in which the two N-bound methyl groups strongly interact with the *ortho*-substituted methyl group. Figure 4 shows the hole-burning spectra of two isomers and it can be seen that they are readily distinguishable.

Figure 4. Hole-burning spectra of the anthracene–dimethyl-*o*-toluidine (An–DMOT) pair, demonstrating the existence of two R-isomers. The vibrational structures of the electronic transitions of the two isomers are clearly different. The probe laser was set at the origins of the two isomers, respectively, which are separated by 97 cm^{-1} from each other; the spectrum shown in (a) is red shifted from that of bare anthracene by 493 cm^{-1} and that shown in (b) is shifted by 396 cm^{-1} . Adapted from Ref. [22a].

The relative populations of the different isomers were calculated from the fluorescence intensities assuming that the fluorescence quantum yields were the same. This assumption, in turn, is based on the experimental finding that the measured decay times were the same for all R-isomers. A semi-empirical method due to Claverie and co-workers [25] was used to calculate the relative energy stabilization of the ground-state isomers (see Section 4.6), and good agreement between the number of experimental and calculated isomers was found. This may eventually allow the tentative assignment of different spectroscopic features to molecular structures with reasonable confidence. It was calculated that the barriers for conversion of one isomer to another on the ground state surface are typically very small, of the order of 1 kcal mol^{-1} . Hence their presence cannot be observed under usual experimental conditions (room temperature, solution phase); jet cooling is the method of choice to discern these fine details. R-isomers are easily transformed in to E-isomers in the excited state: they are mostly observed near the origin, and at excess energies of $0\text{--}200\text{ cm}^{-1}$ they show exciplex emission. This transition is interpreted as a photoinduced electron transfer, the rate of which is discussed in the Section 4.4.

The co-existence of several isomers allows one, in principle, to check possible differences in their photophysical properties. In a recent paper, two-color mass-selective MPI was used to estimate the relative efficiency of the ionization of isomeric forms of DMOT–anthracene adducts [24]. It was found that photodetachment of an electron from the exciplex excited state is about 10 times more efficient than that from LE excited states. A similar observation was made in the case of NaI

[26]. The reason for this difference is not yet obvious, nor is it clear whether this is a general phenomenon. In fact, an opposite trend was reported for the styrene–trimethylamine system [27]. In any case, the difference in ionization efficiency may become another tool for studying gas-phase systems. In cases where several R-isomers co-exist in the jet, some differences were recorded in their photophysical behavior. The change in the rate of R → E isomerization was found to depend on the internal energy in a different way. However, the differences were in general small.

Itoh and co-workers applied the hole-burning method to the study of intermolecular donor–acceptor pairs, linked by a flexible covalent chain. Two of the molecules studied by this group are depicted schematically in Scheme 1. Rotation around single CC (or CO) bonds allows the co-existence of several conformational isomers, which may be present in the jet after the expansion. The goal of these studies was to identify such isomers and study their photophysics. Previous work indicated that several different excitation and emission spectra may be observed from a given sample. In particular, both exciplex-type and locally excited fluorescence were often observed. For the latter it was found that increasing the vibrational energy content of the excited state beyond a certain threshold value led to a gradual increase in the exciplex-type emission. One of the goals of the hole-burning experiments was to find out whether the transition from the locally excited state to the exciplex-type state transition depended on the nature of the different conformational isomers.

The results may be summarized as follows. For 4-(2',3'-dimethylbutenyloxy)-methyl-1-cyanonaphthalene (4-DMB-CNN) [28], hole-burning spectroscopy revealed three different excitation bands. In all, locally excited fluorescence dominated the spectrum at low excitation energies, and a gradual shift to exciplex-type emission was observed as the vibrational energy of the excited electronic state increased. The cyanonaphthalene moiety acts as an electron acceptor and the dimethylbutene moiety as the electron donor. The rate of the transition to the exciplex emission varied among the different isomers, but beyond a certain excess energy (1100 cm^{-1}), no significant difference in exciplex formation could be detected. The three conformers were assigned to the *trans*, *anti-gauche* and *syn-gauche* structures of the molecule.

The 1-(1-anthryl)-3-phenylpropane (1-An-Ph) structure [and the 9-anthryl analog (9-An-Ph)] for which no exciplex emission was observed was studied as a reference system [29]. For both molecules, several conformers are possible, but exciplex-type emission is unlikely, since the two moieties (anthracene and benzene) linked by the flexible propane bridge do not tend to form a donor–acceptor pair. Two major fluorescence excitation series were revealed in both. As the vibrational energy was increased, the decay times of one isomer (isomer I) hardly changed in the range $0\text{--}2000\text{ cm}^{-1}$, whereas a threefold decrease was found in the other (isomer II). The form of the emission spectrum also changed—for both isomers the emission spectrum becomes more diffuse as the internal energy is increased. This change takes place at a higher energy for isomer II than for isomer I. Based on comparison with previous work on rotational conformers (e.g., propylbenzene [30]), it was suggested that isomer I is the *gauche/trans* (*g/t*) isomer, and isomer II is the *trans/trans* (*t/t*) isomer. Torsional motion appears to be important for intramolecular vibrational

Scheme 1 (continued)

energy redistribution (IVR), which is the process responsible for the increased diffuseness of the spectrum and the decrease in fluorescence decay time. In the more tightly folded *g/t* conformer, IVR is restricted, leading to the observed behavior. Simple semi-empirical calculations supported the interpretation.

Several linked molecules in which the donor is an aniline derivative and the acceptor an anthracene moiety were investigated. In the case of anthracene linked to *N,N*-dimethylaniline by a trimethylene bridge, two molecules were investigated. In both the link was to the *meta* (3-) position of the aniline. In one anthracene was linked in the 9-position, (9-anthryl)-3-[*m*-(*N,N*-dimethylamino)phenyl] propane (9-An-*m*-DMA), and in the other the link was to the 1-position (1-An-*m*-DMA). In both cases hole-burning spectroscopy revealed two distinct species, that were assigned to two isomeric forms (possible structures are shown in Scheme 1). The emission spectra of both forms at the origin bands were essentially of the locally excited type. As the internal energy was increased, the exciplex emission spectrum

Figure 5. Changes in the fluorescence spectrum of two isomeric intramolecular adducts of 9-An-*m*-DMA as a function of excitation energy: (a) the isomer having an origin at $26\,644\text{ cm}^{-1}$ and (b) the isomer having an origin at $26\,689\text{ cm}^{-1}$. Adapted from Ref. [19b].

gradually increased in intensity, until it dominated the spectrum. The rate at which the exciplex-type emission increases was different for the two isomers. Figure 5 shows the changes in the fluorescence spectra of the two forms of 9-An-*m*-DMA as the excitation energies are increased. A qualitatively similar situation was observed for 1-An-*m*-DMA. The threshold for the onset of exciplex emission was different for the two forms in the two molecules, as shown in Figure 6. It was suggested that the two species are conformational isomers, and that in order to form the exciplex, the molecule must undergo an intramolecular conformational change that will allow electron transfer. The exact nature of the two conformers could not be established, although on the basis of comparison with the non-exciplex-forming 1-An-Ph and 9-An-Ph, it was proposed that they were probably due to *trans/trans* and *trans/gauche* structures.

The photodynamics of linked systems are thus a sensitive function of their structure, and the excess energy dependence of the electron transfer depends on the details of the intramolecular dynamics. IVR and electron transfer are two important processes that may compete with each other or, conversely, operate in harmony. One way to check the role of IVR without significantly changing the electronic structure of the molecule is by isotopic substitution. The main change is in the vibrational energy-level density. Itoh and co-workers [31] applied this method to the 9-An-*m*-DMA system mentioned above. It was found that the S_1 vibrational energy thresholds for formation of the exciplex were considerably *smaller* in the deuterated molecules than those for the respective protonated molecules. This result is consistent with the assumption that the transition from the locally excited state (the one is initially excited) to the exciplex state, is aided by an increase in the energy level

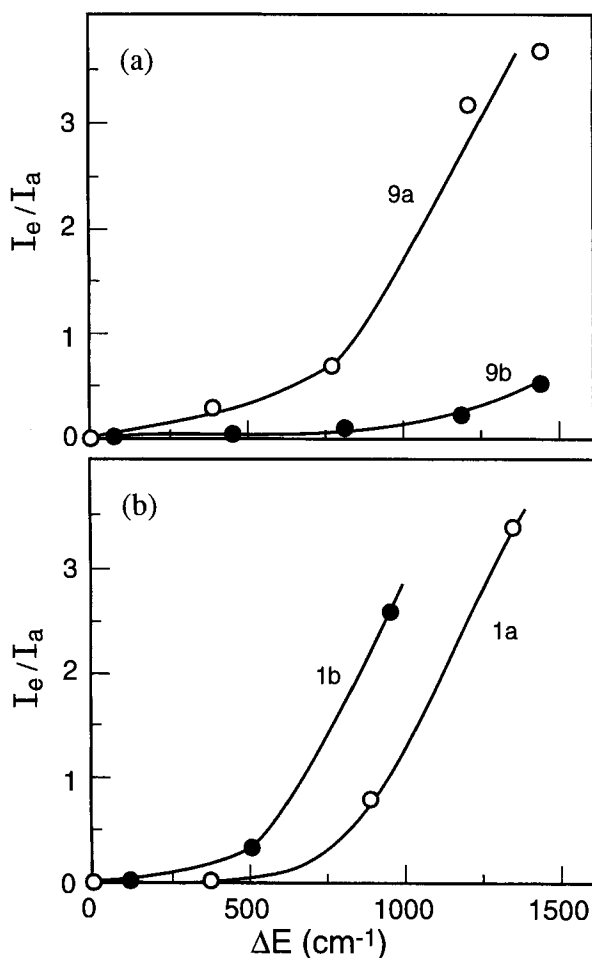

Figure 6. Ratio of the exciplex-type fluorescence intensity (I_e) to that of the locally excited-type fluorescence intensity (I_a) in an intramolecular adduct as a function of excitation energy. The upper panel shows the data for two isomers of 9-An-*m*-DMA and the lower panel for two 1-An-*m*-DMA isomers. The different onsets of exciplex emission are clearly displayed for different isomers. For possible structures of these isomers, see Scheme 1. Adapted from Ref. [19b].

density in the locally excited A^*D complex. The increased density increases the IVR rate, which in turn enhances the rate of internal rotation. Thus, the folding into the 'right' conformer suitable for electron transfer is promoted, leading to faster exciplex formation. This paper [31] therefore provides almost direct experimental evidence for the role of IVR. It would be interesting to find out by direct monitoring of the absorption of the exciplex state whether the rate of its formation is indeed increased upon deuteration.

Figure 7. Schematic energy level diagram showing the principle of the ionization method for detecting electron transfer in gas-phase adducts. Naphthalene cation (the hole donor) is formed by resonance-enhanced two-photon ionization of the neutral. A hole acceptor, whose ionization potential is lower than that of naphthalene, is not ionized, since its S_1 level is not resonant with the UV photons used (ν_1). The vibrational levels of the ionic form of the acceptor are resonant with the naphthalene cation, and accept the hole easily. Detection is by photodissociation, using photons of different frequency (ν_2) that dissociate the naphthalene cation in a resonance-enhanced multiphoton absorption process. Charge transfer is detected by the diminution of the product ion signal in the presence of a suitable acceptor. Adapted from Ref. [32].

4.2.3 Two-color Photoionization

UV absorption spectroscopy is usually not sensitive enough to monitor ions directly in the jet. Even if the original ion pair is somehow dissociated into two separate ions having a characteristic absorption, their detection by high-resolution absorption spectroscopy is often impractical. The nascent product ions are formed in a large number of quantum states, and the small population of a single state cannot be detected with reasonable signal-to-noise ratio.

Ionization is much more sensitive, and may serve in principle as another tool for detecting ions or charge transfer. Levy and co-workers [32, 33] offered a scheme by which charge transfer between two species linked by a suitable bridge may be detected. The scheme is outlined in Figure 7. The donor is ionized by a two-photon

process, in which an excited state acts as a resonance enhancer. A potential acceptor (of positive charge), that has a lower ionization potential than the donor, is linked to the donor. Its direct ionization by the laser is avoided by choosing an acceptor whose intermediate electronic excited state is higher in energy than that of the donor. Once the donor ion is formed, it may transfer its charge to the acceptor. The process is monitored using a second laser source *of a different frequency* that induces fragmentation of the molecule. The second laser is tuned to the absorption spectrum of the donor ion, thus ensuring selective dissociation. In particular, if charge is quickly transferred to the acceptor, no adsorption of the second laser light takes place, and therefore no fragments can be observed. The amount of photoproducts thus serves as a measure for the efficiency of charge transfer.

The method was applied to systems similar to those previously studied in solution [34]. Naphthalene was used as a donor and a variety of molecules as acceptors. The spacer was either a cyclohexane ring or a steroid (androstane). It was found that the idea works in principle: when the other molecule had a higher ionization potential than naphthalene, extensive fragmentation was induced by the second laser, as was the case in the absence of the second molecule (a naphthalene-spacer system). When the donor had a lower ionization potential, fragmentation virtually disappeared. This was interpreted as indicating that complete charge transfer took place within the time resolution of the experiment (~ 2 ns). Attempts to slow the charge transfer by using longer spacers failed. It is likely that applying picosecond laser pulses to this system will enable the charge-transfer rate to be followed in real time.

4.3 Distance Dependence of Charge Separation; Mechanisms

In all systems discussed above, relative motion of the donor and acceptor was possible either since they were separate species or because the 'bridge' connecting them was flexible. Verhoeven and co-workers have studied since the early 1980s systems in which that motion was limited by progressively using more rigid spacers. Early work was in solution, revealing solvent dependence as also found in the classical work of Closs, Miller and co-workers [34] and Wasielewsky [35]. In order to find out whether electron transfer could proceed over long distances in the absence of a solvent, Verhoeven and co-workers prepared a series of compounds that could be studied in a supersonic jet, i.e., under solvent-free conditions. This work was recently reviewed in detail [14], so we shall only summarize the essential features.

Electron transfer was followed by the exciplex fluorescence method: LE and exciplex-type emissions were recorded as a function of internal energy, as in the previously cited papers (Section 4.2). Here, however, the initial excitation was either of the electron donor or the acceptor. The electron-donating power was varied by simple substitution, with minimal interference with the nature of the spacer. Typical donors were *para*-substituted anilines or substituted naphthalenes. Typical acceptors were cyano-substituted naphthalenes (when anilines served as the donors) and dicyanoethylene or dicarbomethoxyethylene when naphthalenes served as donors. Spacers were of varying flexibility: semi-flexible (a piperidine ring which may have a

chair or boat form, attached to a methylene group, for instance **1r**, **2r** and **3r** in Scheme 1). More rigid ones, such as a piperidine ring attached to a vinyl group, for instance **1**, **2** and **3** in Scheme 1), and a most rigid spacer based of a norbornyl bridge, such as **7** in Scheme 1.

In these experiments, excitation was by absorption into the naphthalene moiety, and emission was monitored as a function of excitation energy. In the ground state, the semi-flexible molecule has a stretched conformation, so that the donor and acceptor are separated by at least 5.4 Å. Excitation near the origin led only to LE emission, as in the case of the systems studied by Zewail's [17] and Itoh's groups [19]. Considerable vibrational excitation was required for the appearance of exciplex-type emission. A harpoon mechanism (see Chapter IV.3.2 by Soep and Mestdagh) was suggested to account for the data: the donor sends out the electron to the acceptor over a long distance, and the system folds later on due to the Coulomb attraction between the separated charges. This mechanism was suggested for **1r** because the onset of exciplex emission was observed at 4.8 kcal mol⁻¹, whereas the estimated barrier for folding is 10 kcal mol⁻¹. This mechanism was supported by further experiments: the stretched form of the exciplex could not be observed in the gas phase, but a new emission, centered at 380 nm, was seen in cooled cyclohexane solution. It was assigned to the stretched exciplex by time-resolved studies [36]. The harpoon mechanism was also supported by using a more efficient electron donor (i.e., a molecule with a lower ionization potential). A methyl (**2r**) or methoxy (**3r**) group was placed *para* to the aniline nitrogen. In the resulting molecule, the spacer was identical with that of **1r**, so that the barrier to conformational change was the same. The acceptor unit was also identical, so the excitation spectrum was essentially the same. However, it was found that the threshold energy for exciplex emission was reduced from 4.8 to about 2.1 kcal mol⁻¹. This result is in line with the idea that the barrier to exciplex formation is not due to folding, but an intrinsic barrier to the harpooning. Its height is determined by the crossing point of the two potential surfaces in the classical Marcus mechanism, rather than to a nuclear motion. In terms of Figure 1, it is determined by the height of the crossing point between the LE state of the DA pair, and the exciplex state.

Molecules **1**, **2** and **3** are similar to **1r**, but instead of a flexible single bond connection between the piperidine ring and the acceptor, the vinyl bond makes the system much more rigid. In fact, the donor and acceptor moieties cannot come into close contact by folding. This was verified in solution studies, where the measured dipole moment for the exciplex state (23 D) is consistent with an *extended* rather than folded conformation. In the jet, the excitation spectrum of systems **1**, **2** and **3** were found to be red shifted (by about 5 nm at the origin) and much more congested than for **1r** (Figure 8). The emission spectra are broad and structureless, as expected for an exciplex state, even upon excitation at the longest wavelength, which is assumed to be the origin. The absence of locally excited fluorescence was interpreted as indicating rapid charge separation. From the known radiative lifetime of the parent system (vinylcyanonaphthalene, VCN) and width of the excitation bands, the charge separation rate constant was estimated to be 10¹⁰–10¹¹ s⁻¹ (see Section 4.4 for details).

Even more rigid donor–acceptor systems were constructed using a norbornyl bridge (systems **7** and **8**, Scheme 1). For **7**, the fluorescence excitation spectrum

Figure 8. Excitation spectrum of two acceptor—donor systems, differing only by the spacer module connecting them. The left side shows the spectrum of **2r** (Scheme 1) and the right side that of **2**. Species **2** is the more rigid of the two and its spectrum is more red shifted and congested than that of **2r**. The vibrational progressions shown have a frequency of 13.5 cm^{-1} . Adapted from Ref. [14].

showed no vibrational structure at all, and only exciplex-type emission was observed. The conclusion was that in these systems, the charge-transfer state lies below the LE state, and is directly excited. In terms of Eqs. 1–3, it appears that the transition from the semi-flexible system **1r** to the more rigid molecule **1** and on to the completely rigid **7** involves a gradual change in the relative values of a_{CT} and c_{CT} . One could interpret the results in the time domain: initial excitation is into the LE state, and charge transfer follows. This is the weak coupling approximation, assuming that the donor and acceptor are weakly coupled, so that the system may be considered on the short time-scale characteristic of the light absorption process as being separate entities. An alternative interpretation is that the interaction between the donor and acceptor increases as the system becomes more rigid, so that the exciplex-type and LE states are strongly mixed even in absorption. This approach accounts for the difference between the excitation spectra of **2** and **2r** (Figure 8): the coupling between the two states causes the red shift in the spectrum of **2** compared with **2r**. Rather than viewing the spectrum of **2** as being a pure local excitation, it may actually be excitation of a mixed state, with a large contribution of charge transfer in the excited state. In that case, further time development of the system is controlled by statistics—the exciplex part has a higher density of states than the LE state, and emission is primarily from eigenstates of the exciplex. In solution, the exciplex state is further stabilized, and vibrational relaxation leads to the population of levels below the origin of the LE state.

In the fully rigid system (such as **7**), mixing is complete, and the charge-transfer character dominates even the absorption. It would be interesting to study the photophysics of donor–acceptor systems separated by several norbornyl groups. Such experiments are hampered by the low vapor pressure of these large molecules, but offer an opportunity for studying distance dependence in strongly coupled systems.

Recent experiments [37] showed that electronic energy transfer is very rapid in such systems.

4.4 Rate of Electron Transfer

Tramer et al. [22] discussed the rate of electron transfer in jet-cooled systems. Direct measurement is not always possible, but the rate may be estimated from the changes in fluorescence decay times and from linewidths. The estimate is based on the following data and assumptions:

- Initial excitation is always into the locally excited (LE) state, which then may decay either radiatively back to the ground state or non-radiatively to the exciplex state. Other processes are negligibly slow compared with these two.
- The fluorescence decay time of the locally excited state of the A*D complex (where A is anthracene and D the donor) is about 20 ns, hence the rate constant for depletion of this state, k_A , is $5 \times 10^7 \text{ s}^{-1}$.
- The rate constant for electron transfer is defined as the rate constant of formation of the exciplex state.
- The exciplex state is detected by the exciplex emission, which can be easily distinguished from the locally excited state owing to its much longer decay time (150–300 ns), the large red shift and the broad and structureless spectrum.
- The absence of exciplex emission following photoexcitation in a given system indicates that the rate constant for exciplex formation is at least an order of magnitude smaller, namely $k_{ET} = 5 \times 10^6 \text{ s}^{-1}$.
- If dual fluorescence is observed (both exciplex and LE), then k_{ET} is of the order of magnitude of k_A , namely $5 \times 10^6 \text{ s}^{-1} < k_{ET} < 5 \times 10^8 \text{ s}^{-1}$. Its value may be deduced from direct measurement of the fluorescence decay time of the LE state.

A simple kinetic scheme yields the following equation for the ratio of the integrated exciplex emission intensity, I_{EXC} , to the LE integrated emission intensity, I_{LE} :

$$I_{EXC}/I_{LE} = (k^r_{EXC}/k_{EXC})/(k^r_{LE}/k_{ET}) \quad (4)$$

where k^r_{EXC} is the radiative rate constant of the exciplex, k^r_{LE} is the radiative rate constant of the locally excited state and k_{EXC} is the observed decay rate constant of the exciplex. This expression holds for a short pulse excitation and when $k_{ET} \gg k_{EXC}$. Hence k_{ET} may be deduced if the intensity ratio and the radiative rate constants are known. If only exciplex emission is observed (as is the case when the E-isomer is excited), the electron-transfer rate is at least one order of magnitude larger than k_A , namely $5 \times 10^8 \text{ s}^{-1} < k_{ET}$. An upper limit for the rate constant may be estimated from the linewidths of the excitation bands. Assuming that broadening beyond the rotational envelope width ($\sim 1 \text{ cm}^{-1}$) is due to the electron-transfer rate means that as long as no broadening is observed, k_{ET} is $< 2 \times 10^{11} \text{ s}^{-1}$. When the linewidth exceeds $2 \times 10^{11} \text{ s}^{-1}$ the rate constant may be calculated directly from

the width σ , in cm^{-1} :

$$k_{\text{ET}} = 2\pi c\sigma \quad (5)$$

where c is the velocity of light.

The width of the excitation bands of the E-isomers was about $100\text{--}150\text{ cm}^{-1}$. If that width is due entirely to homogeneous broadening caused by electron transfer, k_{ET} would be of the order of the order of $2 \times 10^{13}\text{ s}^{-1}$. Usually, the observed bands are not purely Lorentzian; they appear to be a superposition of many closely lying bands, whose width is of the same order as their spacing, i.e., about $10\text{--}20\text{ cm}^{-1}$. Hence a more realistic rate constant for the electron-transfer rate constant in these systems is 10^{12} s^{-1} . A similar rate constant is deduced for R-isomers when they are excited to higher vibrational levels. Likewise, the shape of the excitation bands of linked systems [31], when excited to higher vibrational levels, is compatible with similar values.

The excess energy above the origin of the LE state required to reach these high rate constants differs somewhat among different systems. In the intermolecular systems, it is in the range $20\text{--}400\text{ cm}^{-1}$, whereas the linked systems, it may be as high as 1000 cm^{-1} or more. The difference may be due to the more stringent restrictions on the relative motion of the donor and acceptor in the linked systems.

In the linked systems studied by Wegewis and Verhoeven [14], electron-transfer rates were estimated by the same methods—quenching of the acceptor fluorescence and linewidth measurements. The rates were found to vary over many orders of magnitude: in the weakly coupled systems they are $10^7\text{--}10^9\text{ s}^{-1}$ (for the reduced forms **1r**–**3r**), increasing to 10^{11} s^{-1} for the double bond conjugated forms **1**–**3**, and up to 10^{14} s^{-1} for strongly coupled systems such as **7**. The latter conclusion, which is based on linewidths, may be overestimated—if the width of individual lines exceeds their separation, the lines appear to be broad and one sees only the envelope [22]. It may be fortuitous, but these values appear to agree nicely with the results obtained with simpler inter- and intramolecular systems [10, 19, 20].

The next chapter by Ohshima, Kajimoto and Fuke reviews some results obtained with linked systems, in which charge transfer is facilitated by torsional motion around a single bond. Picosecond time-resolved experiments allowed the direct measurement of the decay of the LE state and the rise of the CT state fluorescence. In some cases a third excited state, also characterized as a charge-transfer state, was observed. It was assigned to a charge-transfer state in which the two connected moieties (anthracene and aniline in this case) are twisted from the planar conformation characteristic of the ground state, but not to a fully perpendicular conformation. The photophysics of twisted intramolecular charge-transfer (TICT) states, were studied extensively in the gas phase and in solution (see the previous chapter by Herbich and Brutschy).

Although this chapter deals exclusively with gas-phase systems, it appears appropriate to compare briefly the data with liquid solution work.

In favorable cases, the rate of charge transfer in solutions can be measured directly by following changes in absorption due to the formation of separated ions [38]. Furthermore, the distance dependence of the electron-transfer rate may be

studied extensively—the increased molecular weight makes gas-phase studies extremely difficult.

In some bridged A–br–D systems, in which the donor and acceptor are rigidly linked by a norbornylogous bridge (Ref. [39], pp. 623–626), it was found that the rate of electron transfer could be fitted to an exponential distance-dependent form:

$$k = A \exp(-\beta r) \quad (6)$$

where r is the edge-to-edge distance between A and D. Similar distance dependences of the rate constant in condensed phases were reported by other workers [34, 35] (see also Chapter III.2.1 by Paddon-Row). The charge separation pre-exponential factor A was found to be solvent dependent for a given system. As a typical example, for a group of molecules in which dimethoxynaphthalene (DMN) was a donor, and dicyanovinyl (DCV) the acceptor, the A factor was found to vary between $9.3 \times 10^{13} \text{ s}^{-1}$ for tetrahydrofuran (THF) and $104 \times 10^{13} \text{ s}^{-1}$ for di-*n*-butyl ether (DNBE). The β factor was 0.92 per bond in THF and 1.25 per bond in DNBE [39]. However, the actual values of the rate constants in these two solvents are not necessarily very different. Thus, for eight intervening σ -bonds, they vary only over a factor of 1.4 for these two solvents (4.7×10^{10} for DNBE and 6.7×10^{10} for THF; see Table IV in Ref. [39]). The solvent effects involve several factors, including changes in the overall free energy release, solvent rearrangement, changes in the relative stabilization of excited states, etc. Studies in the gas phase provide a means to study the 'pristine' donor–acceptor system, removing these complications, and thus perhaps to obtain a model for electron transfer that may be compared with quantum mechanical-based theory.

4.5 Exciplexes in Reactive Systems

The role of exciplexes in chemical reactions has been controversial ever since they were discovered. Their most prominent manifestation, the characteristic fluorescence, has actually been taken as an indication that they are not important as reactive intermediates, because of the relatively long decay times. It has been argued that there may be reactive exciplexes which are not observed spectroscopically in emission. Evidence for their presence is deduced mostly from solvent polarity effects.

Jet cooling may reveal weakly fluorescing systems, since some non-radiative decay processes become less efficient in that environment, particularly bimolecular interactions. Thus, exciplexes formed between aromatic molecules acceptors and tertiary amine donors have long been known to fluoresce, whereas under ambient conditions exciplex emission from pairs in which the tertiary amine has been replaced by a secondary or primary amine is rare. Anner and Haas observed exciplex emission from an anthracene–ammonia adduct in a jet [40] and Drescher et al. [41] reported weak exciplex emission from a β -methylstyrene–diethylamine adduct

Figure 9. Fluorescence and REMPI excitation spectra of the styrene-TMA adduct in a supersonic jet. The top panel shows the fluorescence excitation spectrum of the total emission; bands marked S are due to bare styrene. The middle panel shows the fluorescence excitation spectrum observed through a filter transmitting at 385 ± 3 nm and the bottom panel the excitation spectrum of the trimethylamine ion (a fragment of the cluster ion). Two vibronic band systems are clearly observed, one being assigned to an R-isomer and the other to an E-isomer, as shown at the top of the figure. Adapted from Ref. [27].

An attempt to establish the role of exciplexes in a reactive system was made by Kendler and Haas [27]. The fluorescence characteristics of the styrene-trimethylamine (TMA) adduct were studied in a supersonic jet. In the bulk, this system is known to exhibit exciplex emission and also to form photoproducts [42]. In the jet, fluorescence excitation of the STY-TMA 1:1 adduct revealed two isomers, an R-type and an E-type (Figure 9) (labeled n-type and w-type, respectively, in the original paper). The resonance-enhanced multiphoton ionization (REMPI)

Figure 10. Fluorescence spectra of the R- and E-isomers of the styrene-TMA adduct in a supersonic jet. Adapted from Ref. [27].

excitation spectrum is also shown. It is clear that the R-type isomer yields a much stronger ionisation signal than the E-type isomer. The dissociation energy of the R-type isomer in the locally excited state was estimated from MPI measurements to be 1100 cm^{-1} . The emission spectra of the two isomers obtained upon excitation at the origin are shown in Figure 10. Evidently, the R-isomer shows LE-type fluorescence only, while the E-type shows exciplex emission. At higher excitation energies, the R-isomer rapidly develops exciplex emission: at an excess energy as low as 242 cm^{-1} , emission was already largely of exciplex type also from the R-isomer. This finding is reminiscent of the energy dependence of the LE to exciplex conversion in the anthracene-DMA clusters discussed in Section 4.2.

The decay times and the relative fluorescence intensities of both bands were measured as a function of excess energy. Figure 11 reproduces the results. It is seen that in the case of the R-isomer, the decay times and the fluorescence intensity decrease in parallel as the excess energy is increased up to 1100 cm^{-1} . For the E-isomer, the decay time shows a similar behavior, but the fluorescence intensity decreases sharply (by a factor of 10) within 200 cm^{-1} , and then remains almost constant.

These results were rationalized using the energy level diagram reproduced in Figure 12. The scheme is necessarily oversimplified, since it summarizes energy changes along different coordinates under the title 'reaction coordinate'. In the jet, IVR is assumed to be rapid, but the total energy in the cluster is conserved as long as there is no dissociation or photon emission. Initial excitation of the adduct leads

Figure 11. Plot of the decay times and the relative intensities of the fluorescence of the styrene-TMA adduct as a function of excess energy (expressed as frequency shift from the system's origin). Note the different pattern observed for the intensity and lifetime in the case of exciplex-type emission. Adapted from Ref. [27].

either to an excited E-isomer or an excited R-isomer. Both are formed with a relatively large energy excess over the equilibrium structure of the exciplex, which has a different geometry than that of the ground-state adduct. The system is non-stationary in the Franck–Condon (FC) region, and may evolve by different routes. The different excess energy dependence of the exciplex yield vs. decay time may be accounted for as follows: the emitting exciplex is formed in competition with another process, leading to a conical intersection between the excited state and the ground state. Once the emitting exciplex is formed, it may fluoresce in competition with some internal non-radiative processes, such as inter-system crossing. The latter affect the change in decay time, whereas the initial process starting at the FC region determines the yield. The rapid initial decrease may indicate a small barrier on the way to the conical intersection region.

After reaching the conical intersection, the system may evolve to form the radical pair that leads to the final products, or revert back to the ground-state precursors. These processes cannot be observed in the jet, since the products of both routes are formed in a huge number of quantum states, and the detection efficiency of a single product is prohibitively small. This mechanism is also in line with available data in liquid solution. It supports the notion, suggested by some workers [43], that the formation of the exciplex is in competition with formation of stable products. At the same time, it agrees with the important role of the charge-transfer state (or some polar structure), denoted in the scheme as the CT,FC state. The complicated Stern–

Figure 12. Schematic energy level diagram of the styrene–TMA system. The ‘reaction coordinate’ is a general coordinate along which different chemical processes occur. Initial excitation is from the bottom of the ground-state potential surface of the styrene–TMA van der Waals adduct. Excitation is into the Franck–Condon region, which contains an appreciable charge-transfer character and is designated the CT,FC state. This non-stationary state develops along two main routes: one carries the system to the emitting exciplex state, shown on the left. This process competes with rearrangement towards the conical intersection region, in which re-crossing to the ground state takes place. In this region the charge-transfer state is converted to the ground state, where the separated pair may be formed, and also a radical pair, which later leads to the observed products. Note that the dimethylmethyleamino radical $[\text{H}_2\text{CN}(\text{CH}_3)_2]$ may be formed as two isomers, as the nitrogen atom is pyramidal. Adapted from Ref. [27].

Volmer behavior observed for the exciplex emission [43] may also be explained using the model if the quenchers are reactive enough to interact with the transient species formed in the system en route to the conical intersection.

The possible involvement of an exciplex state in quenching the fluorescence of tryptophan and of indole by molecular oxygen has been discussed [44]. No emission was found from this exciplex, but its presence is strongly suggested by photodetachment experiments on the $[\text{indole} \cdot \text{O}_2]^-$ anion in a supersonic jet. The experiment revealed an onset of photoelectrons at about 3.2 eV. This process was assigned to the formation of a neutral charge-transfer complex $[\text{indole}^+ \cdot \text{O}_2^-]$ for several reasons, including the following:

Figure 13. Energy level diagram suggested for the photoinduced electron transfer between molecular oxygen and indole. Adapted from Ref. [44].

- The energetics fit with a reasonable calculation for this ion pair, and not with any other species of the same mass.
- Electron photodetachment from molecular oxygen or from indole can be excluded.
- The absence of clear vibrational structure is consistent with the involvement of a cluster, not a molecule.

The energy level diagram, reproduced in Figure 13, is essentially identical with those suggested for other exciplexes. Emission from exciplexes containing molecular oxygen has not been reported, possibly because of rapid intersystem crossing.

4.6 Modeling

One of the most important motivations for the study of gaseous systems, as repeatedly hinted at, is the hope of obtaining a better connection with theory and theoretical modeling. The structure of solvated adducts and charge-transfer pairs in solution cannot be deduced directly from experimental data. In the gas phase, rotationally resolved spectroscopy provides information on the structure. The method also allows a much better vibrational resolution than liquid-phase spectroscopy, allowing in principle the elucidation of subtle effects such as the role of torsional motion. All of these advantages are enhanced in supersonic jets, where only a small number of quantum states are initially populated.

One of the goals of current efforts in the field is to discriminate between possible ground-state isomers of inter- and of intramolecular adducts. The basic idea behind this effort is that the geometry of the molecular pair involved in the electron transfer may affect the probability of electron transfer. The work of several groups (Piuze, Levy, Itoh) showed that this is indeed the case: several different spectroscopic series of lines were found for a given system, which were assigned to different structural isomers. As discussed in Section 4.2, the barrier to electron transfer appears to be different for different isomers. The task is to correlate the observed spectra with calculated structures.

The simplest model uses atom–atom pairwise potentials, as was done for clusters of molecules with rare gas atoms [45] and with other molecules [46]. The Haas group suggested such models for the anthracene– and perylene–ammonia adducts, in which an electrostatic interaction [47] was added to account for the charge distribution in the molecules [40], and also as for the larger donors (dimethylaniline). The potential is written as

$$V_{\text{Tot}} = \sum_{i=1}^{n_A} \sum_{j=1}^{n_D} (V_{ij}^{\text{vdW}} + V_{ij}^{\text{EL}}) \quad (7)$$

where

$$V_{ij}^{\text{vdW}} = 4\epsilon_{ij} \left[\left(\frac{\sigma_{ij}}{R_{ij}} \right)^{12} - \left(\frac{\sigma_{ij}}{R_{ij}} \right)^6 \right] \quad (8)$$

or

$$V_{ij}^{\text{vdW}} = \beta \exp(-\gamma R_{ij}) - \left(\frac{\alpha_{ij}}{R_{ij}} \right)^6 \quad (9)$$

and

$$V_{ij}^{\text{EL}} = \frac{q_i q_j}{DR_{ij}} + \text{higher terms} \quad (10)$$

Here n_A and n_D are the number of atoms in the acceptor and the donor, respectively, R_{ij} is the distance between atoms i and j and V^{vdW} and V^{EL} are the van der Waals and electrostatic potentials, respectively. The van der Waals potential is often represented by a Lennard–Jones potential (Eq. 8) or by a Buckingham potential (Eq. 9). The parameters α , β , γ and σ are obtained from solid-state crystal data. The leading term in the electrostatic potential is the Coulomb interaction (first term in Eq. 10), where D is the effective dielectric constant (usually $1 \leq D \leq 2$). Other terms may be added to represent induced polarization, etc. [40]. The geometries of the two components of the cluster are obtained from microwave or electron diffraction data or from quantum chemical calculations. It is assumed that these geometries do not change upon adduct formation. An initial guess is made for the structure of the adduct, and then the relative positions of the two (or more) components are varied until a local energy minimum is obtained.

This model was successful in showing that two isomers are expected for the styrene–trimethylamine system [27, 48] (Figure 14). The structures found were consistent with chemical intuition inasmuch as electron transfer may be correlated

Figure 14. Structures calculated for the styrene (S)–trimethylamine (TMA) system: (a) and (b) the two neutral structures having a minimum on the ground-state potential surface, (a) being assigned to the E-isomer and (b) to the R-isomer; (c) structure of the transition state between (a) and (b); (d) structure of the ion pair S^- – TMA^+ . Adapted from Ref. [47].

with well-defined molecular orbitals. In one isomer the lone pair orbital of the amine nitrogen atom (the donor orbital) overlapped nicely with the lowest unoccupied molecular orbital (LUMO) of styrene. In the other structure, the overlap was poor. The method allows also the calculation of the transition state between the two structures. The result for the ground state (a barrier of $\sim 100 \text{ cm}^{-1}$) is consistent with the low barrier observed in the excited state for the $R \rightarrow E$ isomerization. This method can be used only for ground-state systems, for which reasonable potentials have been worked out.

A more sophisticated model has been developed by Milli  and co-workers [49], based on the exchange perturbation method of Claverie and co-workers [25]. This is a semi-empirical, second-order perturbation method: A and D are treated first as separate entities, and then the intermolecular potential is used as the perturbation Hamiltonian. Its most straightforward application is for the ground-state potential. The potential surface of the two components is known (or obtained by quantum chemical calculations). The intermolecular energy is written as a sum of electrostatic, polarization and dispersion terms. The quantum mechanical application requires the consideration of Pauli's principle and antisymmetrization of the wavefunction with respect to electron exchange. It turns out that the polarization exchange term can usually be neglected; therefore, it is possible to write the energies of the ground and excited states of these systems as a sum of terms, as follows.

Ground electronic states

- Electrostatic term: for each component, an *ab initio* calculation is carried out to obtain the wavefunction. The charge distribution is then written as a sum of multipolar, multicentric terms, up to quadrupole. It has been shown that the system can be represented by a relatively small number of point charges, one for each atom and one for each chemical bond [25]. The electrostatic term is the sum of all intermolecular multipole–multipole interactions.
- Polarization term: atomic and bond polarizabilities are taken from experimental data. The polarization energy is the sum of the polarization energies of each component due to the electric field created by the multipoles of the other component.
- Dispersion and repulsion terms: these are calculated as sums of atom–atom contributions, in the same way as in the simpler pairwise potential described by Eq. 7.

Locally excited electronic states

For these, empirical values are usually not available. One calculates first the wavefunction of the excited state, A^* , using SCF-CI techniques. The charge distribution of this state is obtained, and expressed as a sum of multipolar, multicentric terms, up to quadrupole. From this expression, the electrostatic interactions are calculated as in the ground state. The polarization term is harder to calculate, it is often taken to be equal to the ground-state term. The dispersion term may be calculated approximately by considering the interaction between two dipolar distributions due to the excited states of A and D. This approximation is valid when the first excited state

may be described by a single electron excitation, and when the $S_0 \rightarrow S_1$ transition is allowed [50].

Ionic excited states

For these, the electrostatic and polarization terms are dominant. The ground-state wavefunctions of the D^+ cations are calculated; the charge distribution is obtained from them, and used to calculate the interaction. For the anion, it is usually assumed that the extra electron occupies the LUMO of the neutral.

This method was recently applied to the calculation of the ground-state isomers of the anthracene–dimethylaniline derivatives discussed in Section 4.2.2 [22]. It was noted that for each isomer found, the total interaction energy was about the same as the dispersion energy, the other terms largely cancelling each other. In other words, the attractive stabilization of the electrostatic and polarization terms was offset by the repulsive Pauli term. The resulting geometries were different from those based on chemical intuition—the aromatic ring of the aniline was found not to be parallel to the aromatic anthracene. Up to now (early 2000), no high-resolution study of these systems has been carried out experimentally; therefore, the validity of these calculations awaits confirmation.

4.7 Conclusions

The brief survey presented in this chapter demonstrates the wealth of information obtainable from jet-cooled systems. The presence of several conformational isomers has been definitely proven. It may be argued that the small barriers separating them ($50\text{--}400\text{ cm}^{-1}$) mean that in bulk systems rapid exchange takes place between them, so that they are kinetically and spectroscopically indistinguishable. Nonetheless, the fact that electron transfer can be practically blocked by a barrier of only about 50 cm^{-1} in the jet is remarkable. It must mean that in addition to height, the width of the barrier is also important. If the barrier is narrow, tunneling is bound to make electron transfer measurable for such small barriers. The width may be correlated with nuclear configuration and the need to obtain proper overlap between the donating and accepting molecular orbital.

The approximate treatment of these systems composed of an electron donor and an electron acceptor as two separate entities appears to be best justified for the van der Waals adducts. As the interaction between the two components becomes stronger, the distinction between two-component systems and two-state systems becomes hazy. In particular, the rigid systems studied by Verhoeven, Paddon-Row and their co-workers are most interesting. The very strong interaction does not express itself in rapid electron transfer only, but also in energy transfer [37]. In these systems, the concept of stepwise electron transfer between different parts of the molecule may be inappropriate. When the interaction between donor and acceptor states becomes appreciable, the system has to be treated as a single quantum me-

chanical entity. The transition from one state to the other is then perhaps better described as an internal conversion between two electronically excited states of a single system.

The theoretical understanding of electron-transfer processes in molecular systems is still lagging behind experiment. This is understandable in view of the intrinsic complexity of these systems. It appears that in order to design an efficient light-driven electron-transfer system, the complete assembly has to be considered. Electron transfer can be very rapid, but so is recombination. For the systems considered in this chapter to be useful in practical applications, one needs to consider the fate of both the electron and hole formed in the initial step. The multi-bridged systems that have recently been constructed may be the first step in that direction.

Acknowledgments

The Farkas Center for Light Induced Processes is supported by Minerva Gesellschaft mbH. Special thanks and appreciation are due to my co-workers who helped me in untangling some of the mysteries of jet-cooled exciplexes: Drs. Oded Anner, Hanna Zuckermann, Wolfgang Drescher, Eyal Zingher and Shai Kendler and Mr. Ismael Zarura.

5 Isolated Supermolecules

Yasuhiro Ohshima, Okitsugu Kajimoto and Kiyokazu Fuke

5.1 Introduction

Owing to recent advances in gas-phase experimental methods, ensembles composed of a finite number of molecules bound by non-covalent forces, e.g., electrostatic (including hydrogen-bonding) and dispersion interactions, can be formed and studied under isolated conditions. Investigations on electron-transfer (ET) processes that take place in such supermolecular systems are of substantial importance since we can explore the functionality that becomes operative only when the constituents are assembled as a total system. In addition, a precise knowledge of how the composition and configuration of the constituents affect ET can be extracted from studies on the finite ensembles, which are virtually free from perturbations by environments. In particular, the supermolecule approach for the experimental exploration of ET processes is most suitable for combination with detailed quantum mechanical calculations, which have also been developing with extreme rapidity.

The most extensively studied supermolecular systems which exhibit ET are binary gas-phase clusters. In most cases, one constituent has a low ionization potential and thus acts as an electron donor, whereas the other with positive electron affinity acts as an electron acceptor. An electron is transferred from the donor to the acceptor in the system spontaneously or after electronic and/or vibrational excitation. Detailed discussions on the ET processes in such donor–acceptor pairs have already been given in preceding chapters (see Chapters 2 and 4 in this Part). Here, we will mainly focus on supermolecular systems of another type, in which aggregation of more than two constituents is essential for ET to proceed. Even when the electron affinity of an isolated molecule is negative (i.e., the molecule cannot form a stable anion), a group of a certain number of the molecules may act as an electron acceptor. This is entirely due to the collective polarization which stabilizes the electron located inside the molecular ensemble. The ET to such a cooperative electron-accepting unit is strongly related to electron redistribution phenomena in condensed phases, e.g., excitation into the conduction band from an impurity level and formation of

solvated electrons in polar liquids. As an electron donor, two typical systems, i.e., alkali metal atoms and a halide anion (I^- in this case), will be discussed in this chapter. Their simple and well-evaluated electronic energy levels make them ideal electron donors to be investigated. In addition, their low ionization potentials afford the opportunity for the application of various experimental methods utilizing recently developed laser techniques. Because of these advantages, the gas-phase clusters containing alkali metal atoms and the I^- ion have been most actively studied as supermolecular systems displaying cooperative ET.

As a final part of this chapter, we shall briefly discuss the intramolecular ET processes in relatively large aromatic molecules. This is a supplement to Chapter 3 in this Part, in which twisted intramolecular charge-transfer (TICT) phenomena were described for isolated donor–acceptor molecules and their clusters. Here we present the charge-transfer dynamics in some selected anthryl derivatives in which the donor and acceptor parts are linked directly or by alkyl chains, and also microscopic solvation effects on the dynamic properties in their clusters, which were not discussed in the earlier chapter. The emphasis resides on a detailed description of the torsional motions and the solvation structure, which are strongly correlated with the intramolecular charge transfer in these systems.

5.2 Stepwise Charge Separation in Alkali Metal Atom-containing Clusters

Solvated electrons play important roles in chemical and biological phenomena and have been the subject of numerous investigations [1]. Especially the process of excess electron solvation in the alkali metal–polar solvent systems has been one of the central issues. Many experimental and theoretical efforts have been made to understand the nature of solvated electrons and the dynamics of electron solvation in these systems [2]. However, the microscopic properties of solvated electrons are not yet fully understood [3].

Advances in charged-cluster formation have afforded new approaches to microscopic investigations of the solvated electron. Anionic water and ammonia clusters, $(H_2O)_n^-$ and $(NH_3)_n^-$, have been prepared via capture of low-energy electrons by solvent neutral clusters [4, 5]. Their vertical detachment energies (VDEs) have been measured with n up to ~ 70 [6, 7]. On the other hands, Hertel's and Fuke's groups have prepared prototypes such as solvated alkali metal atom clusters, i.e., $M \cdot (H_2O)_n$ and $M \cdot (NH_3)_n$, where $M = Li, Na$ and Cs [8–10]. These clusters serve as a good model for elucidating the microscopic aspect of the electron transfer from the alkali metal atom to solvent molecules. Figure 1 shows a schematic energy diagram for the covalent and ion-pair states in the neutral form and the positive and negative ionic states for metal–solvent clusters as a function of the solvent number (n). The ionic ground states are stabilized monotonically with increasing n , as can be seen from the enthalpies of solvation for the metal ion [11]. For small clusters, the ground state is of the covalent type and expected to be stabilized very slowly

Figure 1. Schematic diagram of the energies of the anion ground state $(M\cdot S)_n^-$, the lowest covalent state $(M\cdot S)_n$, ion-pair state $(M^+S_n^-)$ and cation ground state (M^+S_n) versus n (M = alkali metal atom; S = solvent molecules). The ion-pair state is expected to correlate with the ground state of the solvated electron plus the solvated M^+ ion in bulk fluids. The ground-state electronic character of the neutral cluster changes from covalent to ion-pair type at a certain critical size.

with increasing number of solvents (Figure 1). On the other hand, the energy level of the ion-pair state is more sensitive to the solvation. In analogy with the bulk behavior of an alkali metal in polar fluids [1], the ion-pair state may correlate with the ground state of the solvated electron plus the solvated metal cation. As a result, the electronic character of the ground-state clusters is expected to change from the covalent type to the ion-pair type at a certain critical size. This transition has been investigated by photoionization and photoabsorption experiments on water and ammonia clusters containing a neutral alkali metal atom [8–10, 12]. The solvation of alkali metal atoms has also been probed by photoelectron spectroscopy of the solvated clusters containing alkali metal anions [10, 13–15]. We discuss below the photoionization and photoelectron spectroscopy of these clusters in relation to the electron transfer from an alkali metal atom to solvent molecules and the formation of the solvated electrons.

5.2.1 Alkali Metal Atom Clusters Solvated with Ammonia Molecules

The ionization potentials (IPs) of ammonia clusters containing alkali metal atoms, such as Li [10], Na [8] and Cs [9], have been reported by Hertel's and Fuke's groups. These clusters have been prepared by pickup sources coupled with a heated oven (Na and Cs) or a laser-vaporization source (Li). The $IP(n)$ values decrease almost linearly with $(n+1)^{-1/3}$, which is approximately proportional to the inverse of the cluster radius. Although the IPs of free atoms are different (5.392, 5.139 and 3.894 eV for Li, Na and Cs, respectively), those of the clusters ($n \geq 5$) are almost the same irrespective to the metal atoms. The intercept at $(n+1)^{-1/3} \rightarrow 0$

of the fitted line (1.4 eV) agrees with the photoelectric threshold of liquid ammonia (1.47 eV) and that from the fitted line of VDEs for $(\text{NH}_3)_n^-$ [7]. Fuke and co-workers [9, 10] discussed these observations in terms of the change in the electronic character of the neutral ground-state clusters from the covalent type to the one-center ion-pair type with increasing n (see Figure 1). Stampfli and Bennemann [16] calculated the IPs of metal–ammonia clusters using a polarizable electropole model and suggested a single-center structure for intermediate size ($6 < n < 25$) and a transition to a two-center structure for larger clusters. They predicted that the metal cation and electron are completely separated in the larger clusters, as in the case of bulk solution. *Ab initio* calculations on the geometric structures for both $\text{Na} \cdot (\text{NH}_3)_n$ and $\text{Na}^+ \cdot (\text{NH}_3)_n$ ($n \leq 6$) were conducted by Hashimoto and Morokuma [17]. According to their calculations with the 6–31+G(d) basis set and the Hartree–Fock and second-order many-body perturbation (MP2) methods, both the neutral and ionic clusters with $n \geq 4$ have an interior structure where Na is surrounded by four ammonia molecules in the first solvent shell. These calculations also reproduce the observed IPs reasonably well.

The electronic structures of the neutral clusters have also been investigated by photoelectron spectroscopy (PES) of the solvated clusters of alkali metal anions, $\text{M}^- \cdot (\text{NH}_3)_n$ [10, 13]. The anion clusters have been successfully prepared with a laser vaporization technique coupled with a supersonic expansion method. The PE spectra of mass-selected cluster anions have been studied by using a magnetic-bottle type PE spectrometer [18]. Figure 2 shows the PE spectra of $\text{Na}^- \cdot (\text{NH}_3)_n$ ($n \leq 12$) [13]. The PE spectrum of bare Na^- exhibits a strong band at 0.55 eV and a weak band at 2.65 eV. These bands correspond to the transitions from the ionic ^1S state to the neutral ground (3^2S) and first excited (3^2P) states, respectively. $\text{Na}^- \cdot \text{NH}_3$ exhibits a broad 3^2S -type band at around 0.5 eV, which is an overlap of two transitions. The PE spectrum with higher resolution (not shown) exhibits two separate transitions at 0.42 and 0.67 eV [19]. These bands are ascribed to the transitions of two different isomers. According to the calculations at the MP2 level with extended basis set, $\text{Na}^- \cdot \text{NH}_3$ has two structural isomers with total binding energies (corrected for zero-point vibrations) of 4.3 and 2.9 kcal mol $^{-1}$ [20]. The more stable isomer has a structure similar to that of the neutral complex, in which ammonia molecule is bound to Na^- by the nitrogen atom, whereas in the less stable isomer, NH_3 is bound to Na^- by the hydrogen atoms as in the case of the hydrated anions, such as $\text{Na}^- \cdot (\text{H}_2\text{O})_n$ [10], $\text{Cu}^- \cdot (\text{H}_2\text{O})_n$ [18] and $\text{X}^- \cdot (\text{H}_2\text{O})_n$ ($\text{X} = \text{Cl}, \text{Br}$ and I) [21–23]. The VDEs to the 3^2S -type state of the isomers with the $\text{Na}^- \cdots \text{N}$ and $\text{Na}^- \cdots \text{H}$ bonds have been calculated as 0.35 and 0.65 eV, respectively, at the CCSD(T) level with a frozen core approximation. From these theoretical results, the peaks at 0.43 and 0.67 eV have been assigned to the 3^2S -type transitions of the more and less stable isomers, respectively. The very weak bands at near 2.4 eV shown in Figure 2b have been assigned to the 3^2P -type transitions of the two isomers. The PE spectrum of $\text{Li}^- \cdot \text{NH}_3$ also exhibited a slight red shift in the 2^2S -type band and a large red shift for the 2^2P -type transition, but no indication of the isomers [10, 13]. *Ab initio* calculations also predicted two isomers having $\text{Li}^- \cdots \text{N}$ and $\text{Li}^- \cdots \text{H}$ interactions, but the latter is substantially less stable (>8 kcal mol $^{-1}$) than the former in this case [20].

Figure 2. Photoelectron spectra of $\text{Na}^-\cdot(\text{NH}_3)_n$ clusters ($n = 0-12$), collected using a photodetachment energy of 3.50 eV (355 nm). The spectra are normalized to the peak of the $3^2\text{S}-^1\text{S}$ transition.

For the large Li^- and Na^- clusters solvated with ammonia, both the experimental and theoretical results suggest that the isomer with the metal $\cdots\text{N}$ interaction is much more favored with increasing n as in the case of the neutral clusters. Thus the photodetachment process of the clusters with $n \geq 2$ is considered to involve the transition from the anionic state to near the potential minimum of the neutral states. For $n = 2$, the VDE to the 3^2S -type state does not change appreciably from $n = 1$ (Figure 2c), whereas the 3^2P -type transition shifts to a lower electron binding

energy (EBE) and peaks at about 1.7 eV. For $n \geq 2$, VDEs of the 2S type shift slightly to lower EBE with respect to that of Na^- as seen in Figure 2. The results clearly indicate that the solvation energies of the neutral clusters are larger than those of the anion clusters. The amount of the shift in the 3^2P -type transition is >1.4 eV at $n = 5$ with respect to free Na^- (2.65 eV). The transition to the 2^2P -type state in $\text{Li}^-(\text{NH}_3)_n$ ($n = 2-9$) has also been found to be shifted to lower EBE, as low as 1.4 eV, and almost becomes degenerate with the transition to the neutral ground state (2^2S) for $n \geq 10$ [10]. The large red shift in the 2^2P -type transitions suggests the extensive change in the electronic structure of the metal atom in the clusters. As seen in Figure 2, the successive changes in the VDEs for the 3^2P -type state are >0.2 eV for $\text{Na}^-(\text{NH}_3)_n$ ($n \leq 4$), whereas they are negligibly small for $n = 5-8$. The rapid change in the rate of the shift for this transition between $n = 4$ and 5 indicates the filling of the first solvent shell around Na^- at $n = 4$. The theoretical calculations also predicted that the first solvent shell around the Li and Na atoms is closed with four or five ammonia molecules [17, 24]. Figure 2 also shows that the bandwidth of the 3^2P -type transition increases systematically with increasing n up to 12, although the band shift is almost the same for $n \geq 5$. Moreover, the 2S -type transition stays slightly lower in EBE than that of bare Na^- . The binding energy of the neutral clusters is larger than that of the corresponding anions even after the first solvation shell is closed. These spectral features clearly indicate that the electronic structure of the metal atom is affected further with the addition of ammonia molecules in the second solvent shell. In other words, the valence electron of the alkali metal atom is delocalized over the clusters and interacts directly with the second-shell ammonia molecules. In accord with the above experimental findings, calculations also predicted extensive delocalization of a singly occupied molecular orbital (SOMO) for the clusters with $3 \leq n \leq 6$ [17]. The IPs which are independent of the metal for $\text{M}(\text{NH}_3)_n$ with $n \geq 5$ ($\text{M} = \text{Li}, \text{Na}$ and Cs), as mentioned previously, can be explained by the diffuse character of the SOMO. These results suggest that the alkali metal atom is partially ionized and forms a one-center ion-pair state, which extends over more than the first solvent shell in the clusters.

Recently, Hertel and co-workers investigated the first electronically excited state of $\text{Na}(\text{NH}_3)_n$ with n up to 22 by photodepletion spectroscopy [12]. They observed a drastic decrease in the excitation energy of the 3^2P -type state. The value for the free atom is 16950 cm^{-1} , whereas it is only 6000 cm^{-1} for $\text{Na}(\text{NH}_3)_4$. For larger clusters ($n > 4$), it increases slightly and reaches the bulk value at 6300 cm^{-1} , which corresponds to the absorption of the solvated electron. They have explained the switching of the spectral shift at $n = 4$ as the closure of the first solvent shell. The observed spectral features are very similar to those of the photoelectron spectra of $\text{Na}^-(\text{NH}_3)_n$ (see Figure 2). As mentioned above, both the neutral and anion clusters have similar structures and thus the energy separation between the first and second transitions in the PE spectra corresponds well to the absorption bands of $\text{Na}(\text{NH}_3)_n$ observed by photodepletion spectroscopy.

Farrar and co-workers recorded the photodissociation spectra of the isoelectronic $\text{Sr}^+(\text{NH}_3)_n$ system and observed similar large spectral shifts for the 5^2P-5^2S transition [25, 26]. They carried out a moment analysis of the absorption spectra and found a large increase in the electronic radial distribution in the ground state with

increasing n . Based on the results, they proposed the involvement of an increasing ion-pair character, $\text{Sr}^{2+} \cdot (\text{NH}_3)_n^-$, in both the ground (5^2S) and the first excited (5^2P) electronic states. This argument is similar to that for the alkali metal atom– NH_3 systems. Because a neutral alkali metal atom is isoelectronic with a singly charged alkaline earth metal cation, we might argue that the large red shifts in the absorption bands for $\text{Sr}^+ \cdot (\text{NH}_3)_n$ correspond to the large decrease in VDE for the $\text{Na } ^2\text{P}$ -type state seen in Figure 2. However, since Sr^+ has much larger ionization potential (11.0 eV) than those for alkali metal atoms and has other transitions derived from the d-type atomic orbital between the ground and ^2P -type states, more careful analysis might be required to apply a simple analogy.

5.2.2 Hydrated Clusters of Alkali Metal Atoms

In contrast to the clusters solvated with ammonia, the vertical ionization potentials (IPs) of $\text{Li} \cdot (\text{H}_2\text{O})_n$ [10], $\text{Na} \cdot (\text{H}_2\text{O})_n$ [8] and $\text{Cs} \cdot (\text{H}_2\text{O})_n$ [9] exhibit an anomalous size dependence. For $\text{Li} \cdot (\text{H}_2\text{O})_n$, the IP decreases with cluster size up to $n = 4$ and then becomes constant at 3.12 eV for larger clusters. Similar results have also been observed for $\text{Na} \cdot (\text{H}_2\text{O})_n$ and $\text{Cs} \cdot (\text{H}_2\text{O})_n$ with constant IPs of 3.10 and 3.17 eV ($n \geq 4$), respectively. These values are nearly equal to the estimated photoelectric threshold of bulk ice (3.3 eV) and the VDE of $(\text{H}_2\text{O})_n^-$ [7]. The difference in size dependence of alkali metal clusters with water and ammonia clearly suggests that the IP(n) with $n \geq 4$ in the water systems is determined entirely by the solvents. Several theoretical efforts have been made to interpret the characteristic size dependence of the IPs for $\text{M} \cdot (\text{H}_2\text{O})_n$ [16, 27–29]. Barnett and Landman [28] calculated the geometrical and electronic structures of $\text{Na} \cdot (\text{H}_2\text{O})_n$ ($n \leq 8$) using the local spin density functional method and shown that the structure of the neutral $\text{Na} \cdot (\text{H}_2\text{O})_n$ clusters resembles that of $\text{Na}^+ \cdot (\text{H}_2\text{O})_n$. They also predicted that the saturation of IP for $n > 4$ is due to the formation of a molecular shell around the Na atom for $n \approx 4$, accompanied by exclusion of the valence electron of the alkali metal atom from the hydration cavity. The electron is distributed in a surface Rydberg-like state, where the electron is delocalized and spreads equally around water molecules. Hashimoto and Morokuma [29] calculated the structures and IPs of $\text{Na} \cdot (\text{H}_2\text{O})_n$. According to their calculations, the most stable structure is the surface-type clusters, in which only three or four water molecules are directly bound to the Na atom, and their calculated IPs agree well with the observed values for $n \geq 4$. The calculations also predicted that the excess-electron distribution is localized in the surface region of the clusters at around Na and extend widely in space opposite to the water molecules. With this geometry, the effect of the hydration in the second and/or third solvent shells on the metal atom is expected to be very weak and, as a result, the IPs of these clusters may not change appreciably with increasing n . They also evaluated the IPs of the interior-type structures for $n \geq 4$, but the calculated IPs differ from the experimental values. Recently, Hashimoto and Kamimoto also calculated the geometries and the electronic structures of $\text{Li} \cdot (\text{H}_2\text{O})_n$ ($n \leq 8$) [24]. The theoretical IPs of both the most stable interior and the less stable threefold forms of $\text{Li} \cdot (\text{H}_2\text{O})_n$ were found to be in good agreement with the observed values. Recently, Tsurusawa and Iwata

also examined the IPs and the excess-electron distribution of $\text{Li} \cdot (\text{H}_2\text{O})_n$ using the *ab initio* method and reached similar conclusions [30]. The details will be discussed later.

As in the case of the alkali metal–ammonia systems, the photoelectron spectra of negatively charged water clusters containing alkali metal atoms have been investigated for exploring the electronic structure of the metal atom in neutral clusters. In contrast to metal–ammonia systems, both the $\text{Na}(3^2\text{S})\text{--Na}^-(^1\text{S})$ and $\text{Na}(3^2\text{P})\text{--Na}^-(^1\text{S})$ transitions in the PE spectra of $\text{Na}^-(\text{H}_2\text{O})_n$ ($n \leq 7$) have been found to shift to the higher EBE (see Figure 3). The spectral shifts of the 3^2S -type transition

Figure 3. Photoelectron spectra of $\text{Na}^-(\text{H}_2\text{O})_n$ clusters ($n = 0\text{--}7$), collected using photo-detachment energies of 3.50 eV (355 nm) for $n \leq 1$ and 4.66 eV (266 nm) for $n \geq 2$. The spectra are normalized to the peak of the $3^2\text{S}\text{--}^1\text{S}$ transition.

from that of the bare anion ($3^2\text{S}^{-1}\text{S}$, 0.55 eV) are 0.21, 0.44 and 0.58 eV for $n = 1, 2$ and 3 , respectively. A similar trend in spectral shifts has been observed for the PE spectra of solvated cluster anions such as $\text{Cu}^{-}\cdot(\text{H}_2\text{O})_n$ [18] and $\text{I}^{-}\cdot(\text{H}_2\text{O})_n$ [21, 22]. For $\text{Cu}^{-}\cdot(\text{H}_2\text{O})_n$ ($n \leq 2$), Zhan and Iwata [31] calculated the structures and VDEs using the *ab initio* method and found that the Cu^{-} ion is symmetrically hydrated with $\text{Cu}^{-}\cdots\text{H}$ bonds. On the other hand, the clusters with $\text{Cu}\cdots\text{O}$ bonds were found to be the most stable in the neutral ground state. Thus, the observed blue shift of the photodetachment transition arises from the excitation of the electrostatically stabilized anion into the neutral state with a configuration far from the equilibrium geometry. For $\text{Na}^{-}\cdot(\text{H}_2\text{O})_n$, Hashimoto et al. [20] calculated the structures, total binding energies and VDEs for $n \leq 4$. Their calculations predict that the isomer having symmetrical $\text{Na}^{-}\cdots\text{H}$ bonds is more stable than the other isomer with the $\text{Na}^{-}\cdots\text{O}$ bond by 1 kcal mol $^{-1}$. For $n \geq 2$, the isomers with $\text{Na}^{-}\cdots\text{H}$ bonds are also more stable by 3–5 kcal mol $^{-1}$ than the isomers having only $\text{Na}^{-}\cdots\text{O}$ bonds. Thus, the theoretically predicted structures of $\text{Na}^{-}\cdot(\text{H}_2\text{O})_n$ are different from those for the neutral $\text{Na}\cdot(\text{H}_2\text{O})_n$ clusters having $\text{Na}\cdots\text{O}$ bonds. The calculations also reproduced the observed VDEs reasonably well (0.74, 0.94 and 1.09 eV for $n = 1, 2$ and 3 , respectively) [20]. These theoretical results indicate that the observed PE spectra are mainly due to the isomers with $\text{Na}\cdots\text{H}$ interactions. The much larger electrostatic interaction in the anionic state than that in the neutral state results in a blue shift of VDE. Therefore, the observed features in the PE spectra and the theoretical results indicate that the potential energy minimum of $\text{Na}\cdot(\text{H}_2\text{O})_n$ cannot be accessed by anion PES because of the large difference in the structures of the relevant states. The other interesting feature in the observed PE spectra of $\text{Na}\cdot(\text{H}_2\text{O})_n$ is that there is no appreciable change in the energy separation between the 3^2S - and 3^2P -type states for $n \leq 7$. These results suggest that the electronic structure of the neutral alkali metal atoms is not affected substantially by hydration when the metal $\cdots\text{H}$ interaction is dominant. The 3s electron density should be localized on the Na atom as expected from the theoretical calculations [20].

As mentioned above, the similarity of the geometrical structures between the anionic and neutral clusters is a key to probing the potential energy surface of the neutral state via anion PES. Fortunately, the structures of $\text{Li}\cdot(\text{H}_2\text{O})_n$ in the neutral and anionic forms have been found to be similar to each other. These clusters have similar interior structures with $\text{Li}\cdots\text{O}$ bonds and hydrogen-bonding networks for solvent water molecules for $n \leq 8$ [20, 24]. Hence these clusters are good targets to explore the electronic structure of the neutral clusters by PES. Figure 4 shows the PE spectra of $\text{Li}^{-}\cdot(\text{D}_2\text{O})_n$ ($n \leq 10$) recorded at a photon energy of 3.50 eV. The spectra of $\text{Li}^{-}\cdot(\text{H}_2\text{O})_n$ have been found to be essentially the same as those of $\text{Li}^{-}\cdot(\text{D}_2\text{O})_n$. The bare Li^{-} exhibits a strong band at 0.62 eV and a weak band at 2.47 eV, corresponding to the $\text{Li}(2^2\text{S})\text{--Li}^{-}(^1\text{S})$ and $\text{Li}(2^2\text{P})\text{--Li}^{-}(^1\text{S})$ transitions, respectively. The spectrum for $\text{Li}^{-}\cdot\text{D}_2\text{O}$ consists of two peaks at 0.56 and 1.97 eV, corresponding to the two transitions in Li^{-} . Interestingly, these bands are shifted to the lower EBE with respect to those of bare ion by 0.06 and 0.5 eV for the 2^2S and 2^2P transitions, respectively. For $\text{Li}^{-}\cdot\text{D}_2\text{O}$, the calculations have predicted two isomers with $\text{Li}\cdots\text{O}$ and $\text{Li}\cdots\text{D}$ bonds, of which the former is more stable than the

latter by about 5 kcal mol⁻¹ [20]. The VDEs of the 2²S-type states are calculated to be 0.45 and 0.85 eV for the stable and less stable isomers, respectively, at the CCSD/6-311++G(d,p)//MP2/6-311++G(d,p) level. From these theoretical predictions and the experimental results on the alkali metal–ammonia clusters, the observed bands have been assigned to the transitions of the 1:1 complex with Li···O interaction. The large shift in the Li(2²P)–Li⁻(¹S) transition (ca. 0.5 eV) from the bare atom indicates a large increase in the binding energy between the Li atom and the solvent molecule in the first excited state (as large as ca. 0.90 eV) owing to a much larger electron-transfer interaction.

The PE spectra for Li⁻·(D₂O)_n with *n* ≥ 4 show that the band to the 2²S-type state shifts slightly to the red with respect to the 1:1 complex, while the band to the 2²P-type state shows much larger red shift, 1.43 eV for *n* = 4, as shown in Figure 4c. The theoretical calculations have predicted that the most stable isomers of these clusters also have Li···O bonds, and the other isomers with Li···D bonds become energetically unfavorable with increasing *n* [20]. Moreover, the calculated VDEs to the 2²P-type state for the most stable isomers have been found to be close to 0.50 eV, whereas those of the less stable isomers become larger with increasing *n* as in the case of Na⁻·(H₂O)_n shown in Figure 3. From the comparison of these experimental results with the theoretical data, the observed PE spectra for *n* ≤ 10 have been assigned to the transitions of the most stable clusters.

The spectral features in the PE spectra of Li⁻·(D₂O)_n (*n* ≤ 4) are similar to those of Na⁻·(NH₃)_n, and completely different from those of Na⁻·(H₂O)_n mentioned previously. The observed red shifts of the 2²S-type transition with respect to that of the bare anion clearly indicate that the solvation energies of the neutral clusters are larger than those of the anionic forms. The large binding energy in the neutral forms has been ascribed to the extensive charge-transfer interaction induced by the strong Li···O interaction. The large reduction in the 2²P–2²S energy separation, suggesting a complete change in the electronic structure of the Li atom in the clusters, may support this conclusion. These experimental findings are consistent with recent theoretical calculations on the distribution of the 2s valence electron of Li in neutral Li·(H₂O)_n clusters reported by Hashimoto's and Iwata's groups [24, 30]. According to the calculations, the valence electron of Li in the *n* ≤ 2 clusters is strongly polarized in the direction opposite to the water molecules, but is mainly distributed around the Li atom. In Li·(H₂O)₄, the electron distribution is further altered and the electron density is separated from the Li atom; it extends mostly on and between the H₂O molecules. The calculations also reproduced the observed IPs for *n* ≤ 4 with sufficient accuracy. The rapid decrease in IPs has been ascribed to the redistribution of the valence electron on the surface of the cluster where the positive charge is screened with water molecules. Therefore, the red shift of the 2²S- and 2²P-type transitions of Li·(H₂O)_n observed in the PE spectra and the theoretical calculations suggest that the Li atom is gradually ionized with increasing *n* up to 4.

For Li·(H₂O)_n (*n* ≥ 5), both the 2²S- and 2²P-type transitions come to be shifted to the *higher* EBE with respect to those with *n* = 4. This trend may indicate that the first solvent shell around Li is closed with four water molecules in both the neutral and anionic forms. In addition to the spectral shifts, the bandwidths of these transitions become broader for *n* ≥ 5. The gradual increase in the bandwidth indicates

Figure 4. Photoelectron spectra of $\text{Li}^-\cdot(\text{D}_2\text{O})_n$ clusters ($n = 0-10$), collected using a photodetachment energy of 3.50 eV (355 nm). The spectra are normalized to the peak of the $2^2\text{S}-1^1\text{S}$ transition.

an enlargement of the structural difference between the anionic and neutral ground states after the first solvent shell is closed. According to the calculations [24, 30], a $2s$ valence electron of Li in the $n \geq 5$ clusters is squeezed out from the first solvent-shell cavity, forming $[\text{Li}\cdot(\text{H}_2\text{O})_4]^+$, and starts to be trapped on the second-shell waters. For $n = 8$, the electron is localized near the cluster surface to form a two-center ion-pair structure. The electron that has escaped from the first solvent shell interacts with some dangling H atoms in the second-shell waters [30]. Because of the electron $\cdots \text{H}-\text{O}$ bond interaction in the second shell in $\text{Li}\cdot(\text{H}_2\text{O})_n$ ($n \geq 5$), their structures may be distorted from a centrosymmetric form. The extent of the electron localization in the anion clusters is expected to be much smaller because the excess electron in the anion may occupy the same highest occupied orbital being accommodated by the valence electron and they may repel each other. This difference in the electron-localization modes may cause a significant change in the structures of the anion and neutral clusters and may reflect on the bandwidth and also the shift of the PES bands. Although the theoretical results on the larger anion clusters are not available at present, these arguments seem to suggest that the formation of the two-

center ion-pair state in the neutral clusters may be responsible for the observed switching of the spectral shift.

5.3 Charge Transfer in Solvated Anion Clusters

As the second topic in this chapter, the following charge transfer in anionic cluster systems is discussed in this section:

where $\text{X}^{\cdot-}$ and S represent a stable valence anion and a solvent molecule, respectively. In the $\text{X}^{\cdot-}(\text{S})_n$ state, the negative charge is localized exclusively in the $\text{X}^{\cdot-}$ anion core. Even if all the valence anionic states of S are unstable to autodetachment, there can be a different bound (or quasi-bound) anionic state, denoted $[\text{X} \cdot (\text{S})_n]^-$ here, in which the excess electron resides in a diffuse orbital extending over the whole cluster system. Such a diffuse electron trapping can originate from the electrostatic interaction between the excess electron and molecules/atoms. For example, a polar system with a sufficiently large permanent dipole moment can support a weakly bound anionic state, which is well known as a ‘dipole-bound state’ [32]. The excess electron can also be trapped at polar parts in the system, such as a cavity surrounded by dangling hydrogens in anionic water clusters [33, 34]. Even in totally non-polar systems such as pure rare-gas atom clusters, the polarization-induced electrostatic field is strong enough to support a diffuse bound or quasi-bound state [35–39].

If the localized state, $\text{X}^{\cdot-}(\text{S})_n$, is the most stable electronic state in the anion cluster, photoexcitation from the $\text{X}^{\cdot-}(\text{S})_n$ ground state to the diffuse $[\text{X} \cdot (\text{S})_n]^-$ excited state is inherently accompanied by a substantial change in the electronic character and charge distribution. If most of the negative charge is distributed over the solvent moiety, the diffuse anionic state can be represented by $\text{X} \cdot (\text{S})_n^-$ and we may regard the transition from $\text{X}^{\cdot-}(\text{S})_n$ to $[\text{X} \cdot (\text{S})_n]^-$ as a kind of ‘charge transfer to solvent’ (CTTS). This is a cluster analog for CTTS of solvated anions in condensed phases. The observation of CTTS states in solutions dates back to the 1920s [40]. Stable anions, e.g., halide ions, OH^- and NO_3^- , exhibit distinct absorption in the UV region, whose excitation energy is insufficient for the valence excitation of the anion or the creation of free electron [41, 42]. This absorption has been assigned to the electron ejection from the anion into the solvent, i.e.,

Since the beginning of its observation, CTTS has attracted much attention owing to its great importance as a source of solvated electrons, and has been explored extensively in relation to the solvation dynamics of electrons [43–51]. The cluster analog in Eq. 1 has been expected to be a useful model system for microscopic

characterization of CTTS, and has become a focus of recent studies with state-of-the-art methodologies [52]. In such studies, I^- was chosen as a reactant anion because of its stability, the excess electron being bound by 3.04 eV relative to the neutral $\text{I}(^2\text{P}_{3/2})$. The solvents thus far examined are relatively small polyatomic molecules with substantial polarity, e.g., acetone [53], acetonitrile [54] and water [55, 56], in addition to a highly polarizable closed-shell atom, Xe [57]. The studies on I^- clusters with organic molecular solvents, hydrated clusters and $\text{I}^-(\text{Xe})_n$ will be described in some detail in this section.

5.3.1 Dipole-bound Excited States in I^- Clusters Solvated with Small Organic Molecules

Experimental studies on charge-transfer excitation from the localized ground state to the diffuse dipole-bound excited state have been pioneered by Johnson and co-workers [53]. They studied the I^- -acetone cluster via PES and photofragmentation action spectroscopy. The anion cluster was formed by expanding a mixture of several atmospheres of Ar with vapor of methyl iodide and acetone, which was intersected by a 1 keV electron beam at the throat of the expansion. For PES, the anion complex thus formed was mass selected and irradiated with 4.66 eV laser light. The kinetic energy of the ejected electron was analyzed using a time-of-flight (TOF) spectrometer. After the electron-detachment threshold had been determined by PES, photofragmentation was examined by scanning an excitation laser around the detachment threshold. Action spectra for both anionic and neutral products were recorded. The anion fragments were detected in a mass-selected manner by using a tandem TOF spectrometer, while all the photo-neutrals were monitored with a fast neutral detector.

The PE spectrum of I^- -acetone shows a single band peaking at an electron binding energy of 3.49 eV. This value corresponds to the vertical detachment energy (VDE) of the anion complex. Stronger binding (by 0.43 eV) with almost identical bandshape relative to the free I^- ion confirms that the ground-state complex is essentially the intact I^- ion stabilized by solvation with acetone. The action spectrum for the neutrals has an onset about 0.12 eV below the VDE. This indicates the existence of an electronic state slightly below the electron-detachment threshold, which is typical of a dipole-bound state [32]. The action spectrum peaks at the VDE and gradually declines at higher energy, probably owing to the direct photodetachment. It has been noted that the neutral action spectrum is approximated as the absorption spectrum of anion clusters, since all the following reaction channels (Eqs. 3a–c) after photoexcitation produce neutral products:

where $S = \text{acetone}$ in this case. Product analysis has shown that only $(\text{acetone})^-$ is formed as an anion fragment, indicating predominance of channel 3b over 3a. The action spectrum monitoring $(\text{acetone})^-$ indicates a band which looks similar to that in the PE spectrum. Especially, the shapes in the lower energy region are fairly close each other, except that the action spectrum is shifted slightly lower (by ~ 10 meV). In the region above the VDE, the $(\text{acetone})^-$ action spectrum falls more sharply than the PE spectrum. This has been explained by the efficient autodetachment in vibrationally excited states of the dipole-bound complex. The dissociation into I and $(\text{acetone})^-$ after photoexcitation below the VDE should proceed via thermal decomposition of vibrationally hot clusters or excitation to a repulsive region of the I-acetone neutral potential energy surface. In any case, the remarkable result that the excess electron is preferentially trapped by acetone rather than I with much larger electron affinity indicates strong similarity of the dipole-bound state of the $[\text{I} \cdot (\text{acetone})]^-$ precursor and the $(\text{acetone})^-$ product.

To confirm the generality of a diffuse dipole-bound excited state existing in anion clusters with polar solvent molecules, Johnson and the co-workers extended the study to I^- clusters solvated with acetonitrile molecules, i.e., $\text{I}^- \cdot (\text{CH}_3\text{CN})_n$ ($n = 1$ and 2) [54]. Acetonitrile was chosen as a suitable solvent, since it has no anionic valence state lying in the lower energy region and its dipole moment is large (3.92 D).

Experimental methods for exploring excited dipole-bound anions are almost identical for the study of $\text{I}^- \cdot (\text{acetone})$ mentioned above. The VDEs were determined via PES, then the action spectra for negative and neutral photoproducts were observed across the VDEs for $\text{I}^- \cdot (\text{CH}_3\text{CN})_n$ ($n = 1$ and 2). The behavior of the $n = 1$ cluster is remarkably similar to that of the $\text{I}^- \cdot (\text{acetone})$ complex. First, the PE spectrum of $\text{I}^- \cdot (\text{CH}_3\text{CN})$ indicates a band with almost the same shape as the bare I^- band, but shifted by 0.48 eV higher electron binding energy. Second, the absorption cross-section has an onset 0.1 eV lower than the VDE, and increases significantly toward a peak just below the detachment threshold. Third, $(\text{CH}_3\text{CN})^-$ is the only anion product after photoexcitation below the VDE. Fourth, the band appearing in the $(\text{CH}_3\text{CN})^-$ action spectrum is almost identical with that in the PE spectrum, besides the slight red shift. In addition, the PE spectrum of the product $(\text{CH}_3\text{CN})^-$ ion was obtained by a two-color experiment, in which $\text{I}^- \cdot (\text{CH}_3\text{CN})$ was excited into the dipole-bound state by the first laser (at 355 nm) to produce $(\text{CH}_3\text{CN})^-$ and the product was sequentially irradiated with the second laser (at 1064 nm) to photodetach the excess electron. The PE spectrum shows a sharp peak at almost zero electron binding energy, confirming that the $(\text{CH}_3\text{CN})^-$ thus generated is in the dipole-bound ground state.

The notable difference from the $\text{I}^- \cdot (\text{acetone})$ complex is the much larger enhancement of absorption just below the VDE, which corresponds to the excitation to the diffuse $[\text{I} \cdot (\text{CH}_3\text{CN})]^-$ state. The enhancement has been explained as being due to the much larger dipole moment of acetonitrile than acetone, which makes the dipole-bound electron more localized, resulting in larger overlap between the diffuse orbital and the HOMO of the ground state, mostly localized in the 5p orbital of I^- . This implies that, for clusters with more than two solvent molecules, the absorption cross-section to an excited dipole-bound state provides information on the net dipole moment of the solvent system. This has been demonstrated in the $\text{I}^- \cdot (\text{CH}_3\text{CN})_2$ clusters, as mentioned below.

The PE spectrum of $\text{I}^- \cdot (\text{CH}_3\text{CN})_2$ has shown some different features to the bare I^- and $\text{I}^- \cdot (\text{S})$ anions (S = acetone and acetonitrile). It consists of two bands at 3.88 and 4.02 eV in binding energy, of which the higher one (denoted band I) is much stronger than the other (band II). The shift for the major peak (I) relative to bare I^- is exactly twice of that for $\text{I}^- \cdot (\text{CH}_3\text{CN})$, strongly implying symmetric solvation of the I^- core by two CH_3CN , i.e., the solvent molecules reside in equivalent sites, as $\text{NCCH}_3 \cdots \text{I}^- \cdots \text{CH}_3\text{CN}$. Two possible origins of the minor peak (II) have been considered, i.e., a hot band associated with the stronger peak or an isomer with a different configuration. The observed neutral action spectrum also indicates two bands, but the shapes and the relative intensities are very different from those in the PE spectrum. This observation supports the co-existence of two structural isomers in the anion ground state, since a hot band should have a similar shape to a cold band with relative intensity the same as that in the PE spectrum. The lower band (denoted band A) has a feature typical of a dipole-bound excited state, correlating with the detachment threshold of band II in the PE spectrum. The higher band (band B) is much weaker and peaks at the VDE of band I in the PE spectrum.

The large absorption cross-section for band A indicates that the structural isomer with ~ 3.9 eV electron binding energy should have a very large net dipole moment for the solvent unit. An asymmetric colinear geometry, as $\text{I}^- \cdots \text{CH}_3\text{CN} \cdots \text{CH}_3\text{CN}$, has been considered as most probable. The symmetric solvated isomer ($\text{NCCH}_3 \cdots \text{I}^- \cdots \text{CH}_3\text{CN}$) has no net dipole moment in a linear configuration, and the slightly bent form or large-amplitude librations of two dipoles have been suggested to support the dipole-bound state correlating with the weak band (B). Anion photoproduct analysis has provided further information for structural assignments. Photoexcitation into band A produces both CH_3CN^- and $(\text{CH}_3\text{CN})_2^-$ anions but no I^- , whereas excitation into band B results only in electron detachment. The $(\text{CH}_3\text{CN})_2^-$ thus generated should be a dipole-bound cluster with a linear $(\text{CH}_3\text{CN} \cdots \text{CH}_3\text{CN})^-$ configuration. This strongly supports colinear geometry in the asymmetric isomer, as the photodissociation from the $[\text{I} \cdot (\text{CH}_3\text{CN})_2]^-$ state cannot induce a large geometrical change. The difference in the electron binding energies corresponds directly to the anion stability, as the van der Waals binding energies in the neutral isomers should not be very different. Hence the symmetric isomer is more stable than the asymmetric isomer by 0.14 eV.

The most important point in this study is that the dipole-bound excited states of the $\text{I}^- \cdot (\text{CH}_3\text{CN})_2$ cluster cannot be considered as a result of further solvation of the $[\text{I} \cdot \text{CH}_3\text{CN}]^-$ ion core. Instead, the nature of diffuse excited states is determined by the entire arrangement of solvent molecules around the solute anion, as mentioned above. This situation is more akin to CTTS in bulk solutions than solvated ion cores, which are common to most ionic clusters and electrolytic solutions without photoexcitation.

5.3.2 CTTS Precursor States in $\text{I}^- \cdot (\text{water})_n$ Clusters

Evolution of the diffuse excited state with increasing degrees of solvation is of great interest with respect to the correlation with the bulk CTTS. The first examination of this issue was conducted with the I^- clusters solvated with water molecules. John-
